

USING HIGH RESOLUTION DATA TO INVESTIGATE THE VARIABILITY OF GG CARINAE SYSTEM

Maria Auxiliadora Machado,¹ Francisco Xavier de Araújo,¹ Dalton de Faria Lopes,¹ and Claudio Bastos Pereira¹

GG Carinae is a peculiar emission line object classified as a B[e] star. Using high resolution data we confirm that GG Carinae is at same time a binary system and a variable star.

GG Carinae was classified by Lamers et al. (1998) as a B[e] star and also is pointed out as a binary system. So, any investigation to determine its parameters requires an detailed analysis in order to know and to separate the effects of each component. Gosset et al. (1984) used Fourier Analysis in the data obtained from photoelectric photometry of both the standard UBV and Strongren system and calculated a period of 31^D.02. According the authors there are two possible scenarios for GG Carinae: i) GG Carinae has an assymetrical atmosphere where the P Cygni profiles are formed and the brightness variation would be caused by extinction due it is moving inside a nebulae; ii) the companion of GG Carinae must have a intense hydrogen-rich hot spot which orientation respect to observer would be responsible by the light variation. It is important to note that there is no conclusion about its binary nature as well as to the physical structure of his envelope. This unconvulsive scenarium and the desire to take GG Carinae in account in our investigation about massive stars motivated us to analyse this star.

In this work we present recent optical high resolution observations taken over the lightcurve of GG Carinae obtained by Gosset et al. (1985). These spectra show new aspects about the binary nature of GG Car and in special about the intrinsic variability of the main star wich has been predicted by Kruytbosch (1930).

The high resolution data were taken with the Fiber-fed Extended Range Optical Spectrograph (FEROS) that is a Echelle spectrograph with a spectral resolving power of $R = 48\,000$ corresponding to 2.2 pixels of $15\mu\text{m}$ and with a wavelength coverage from 3600\AA to 9200\AA .

The main aspects observed on the spectra of GG Carinae were:

1. The formation of a second absorption compo-

nent on Balmer and on some He I lines.

2. The variation on equivalent widths of Balmer, He I and Fe II lines.

Analyzing the phase variations for H_δ , H_γ and the He I lines, we can see that the second absorption component present in these lines are not in phase and cannot be associated to an occultation. However, when we analyse this variability over the time, we see that the evolution of the shape of the profiles seems indicate a variation on density structure of the wind. Figure 1 show the variations of the He I λ 5876 Å in the time. However the behavior of the stellar component of the resonance doublet of Na I λ λ 5890-5896 as well as the Fe I lines are also in phase, confirming the presence of a companion.
