ABSTRACT—We report the oldest fossil occurrence of freshwater potamolepid sponges (Demospongiae, Spongillina, Potamolepidae) to date, originating from middle Eocene lake sediments accumulated in the Giraffe kimberlite maar, northern Canada. Sponges are represented by strongyle spicules that are gemmuloscleres. These are described herein as belonging to a new species, *Potamophloios canadensis*. Because the most similar extant potamolepid sponges inhabit subtropical to tropical water bodies, these observations provide further evidence of biogeographic reorganizations in response to warm high-latitude Eocene paleoclimates.

INTRODUCTION

MOST OF the over 8,000 living species of sponges are marine (Hooper and Van Soest, 2002), augmented by a large number of fossil taxa (Hooper et al., 2011). In contrast, there are only about 200 species of freshwater sponges, attributed to six families and 45 genera, all of which belong to the class Demospongiae (Manconi and Pronzato, 2008). Only 18 species are known from freshwater habitats in Europe (Pronzato and Manconi, 2001), whereas modern North American freshwater sponges are represented by 27 species in 11 genera (Frost et al., 2001). The highest diversity of freshwater sponges is found in the Neotropics, especially in South and Central America and the Caribbean, with 56 species in 21 genera (Manconi and Pronzato, 2008). The diversity of freshwater sponges is probably underestimated in many regions due to a paucity of studies, as testified by the number of new taxa revealed from regions that were thought to have been thoroughly investigated (Manconi and Pronzato, 2005; Volkmer-Ribeiro et al., 2009, 2010; Nicacio et al., 2011; Ruengsawang et al., 2012).

Marine demosponges appear in the Neoproterozoic (i.e., 555–600 Ma, Reitner and Woerheide, 2002) and have a relatively continuous fossil record since the Cambrian (Pisera, 2006; Hooper et al., 2011 and references therein). In contrast, the fossil record of freshwater sponges consists of only a few genera and species from shorter and often isolated time-slices separated by lengthy barren intervals (Pisera and Saez, 2003). The oldest freshwater sponges, reported from Permo-Carboniferous lake deposits in Europe (Schindler et al., 2008), are represented by simple oxaeas forming spiculites. A similar type of preservation is associated with the Late Jurassic freshwater sponge *Eospongilla morrisonensis* from the western U.S. (Dunagan, 1999).

The earliest record of well preserved freshwater sponges includes intact gemmules (resting bodies) from the Lower Cretaceous of South America (Ott and Volkheimer, 1972; Volkmer-Ribeiro and Reitner, 1991). The Paleogene record of freshwater sponges is better represented with findings from several continents (see Pisera and Saez, 2003 and references therein). Eocene freshwater sponges, in particular, are relatively well documented from European sites including the famous Messel oil shales (Müller et al., 1982; Richter and Wuttke, 1995,

1999), and the Eckfeld maar (Gruber, 1994). The former locality has yielded a range of new taxa, including *Ephydatia guttenbergiana* (Müller et al., 1982) and *Lutetiospongilla heili* (Richter and Wuttke, 1999). Additionally, the species *Ephydatia kaiseri* (gemmulae observed in thin section) has been described from the “prämitteleozäne” of South Africa (Rauff, 1926; Arndt, 1936).

Today, freshwater sponges are found on all continents except Antarctica and occur in an extremely wide range of habitats (Manconi and Pronzato, 2002, 2008). Some species have apparent cosmopolitan distributions, but there are equally as many endemic forms restricted to ancient freshwater bodies, such as Lake Baikal and lakes of the East African rift (Manconi and Pronzato, 2002, 2008; Meixner et al., 2007). In this paper, we report the first occurrence of a fresh-water siliceous potamolepid demosponge from the middle Eocene, and describe it as a new species. These microfossils provide new constraints on the evolution of this sponge lineage by extending their geological range considerably, and furthermore provide ancillary paleoecological evidence for the character of high-latitude lake ecosystems under equable climatic conditions.

GEOLOGICAL SETTING

The Giraffe fossil locality (Nowicki et al., 2004; Wolfe et al., 2006; Siver and Wolfe, 2009; Doria et al., 2011) comprises an organic sediment sequence that accumulated post-eruptively in a kimberlite diatreme having intruded the Slave Craton of the Canadian Shield 47.8 ± 1.4 Ma (Fig. 1). Immediately following kimberlite phreatomagmatism, a water body formed in the crater, and limnic sediments began to accumulate. It is difficult to estimate the dimensions of the lake, but comparisons to similar kimberlites on the Ekati diamond property suggest a diameter between 100 and 200 m. There is no evidence of multiple phreatomagmatic events. Approximately 50 m of lacustrine sediment (laminated shales and massive organic mudstones with occasional presence of nodular opal-A) comprise the lower maar facies, which is succeeded by terrestrial sediments dominated by *Metasequoia* (Coniferae, Cupressaceae) foliage and wood. Two calc-alkaline airfall tephra layers occur at the transition between lacustrine and terrestrial sedimentation. These ashes have been dated by

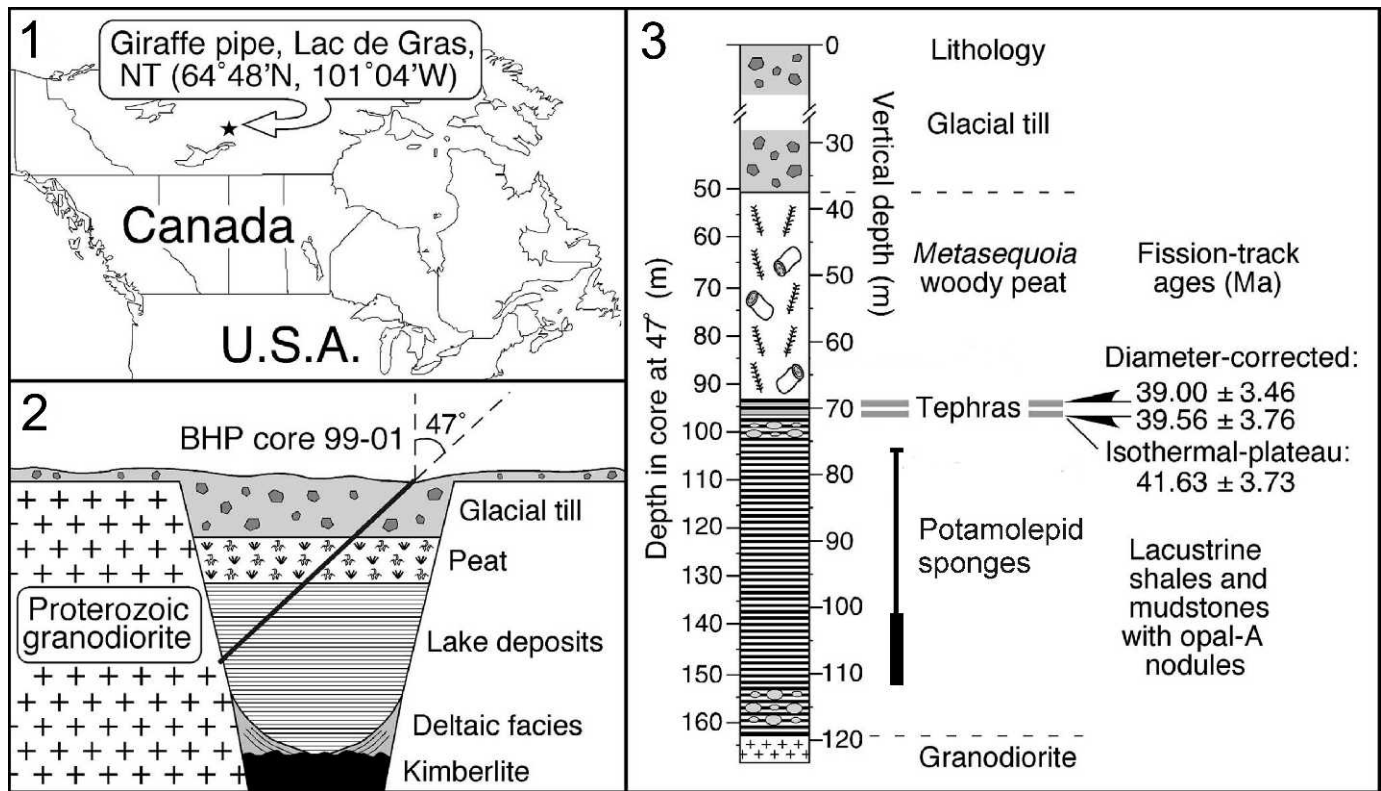

FIGURE 1—Location map and stratigraphy of the Giraffe fossil locality. 1, location; 2, schematic stratigraphy; 3, lithostratigraphy and potamolepid sponges occurrences. The width of the vertical bar indicates the relative abundance of sponge spicules.

fission-track analysis, yielding concordant dates that produce a weighted mean of 37.84 ± 1.99 Ma (Doria et al., 2011). This implies that the entire lacustrine sequence is middle Eocene (Lutetian Stage) in age. Due to the thermal and tectonic stability of the locality, diagenetic alteration of fossil material is minimal, and accordingly all organism groups investigated thus far display outstanding preservation (Wolfe et al., 2006; Siver and Wolfe, 2009; Siver et al., 2010).

MATERIAL AND METHODS

The investigated material originates from a drill-core obtained in 1999 by BHP Billiton Diamonds Inc. during diamond exploration. The core was collared at 47° but depths reported here have been converted to their vertical equivalents (Fig. 1). The present study is based on isolated spicules obtained from sediment samples (~200 mg) following treatment with 30% H_2O_2 , repeated washings with deionized water, and final suspension in reagent grade propanol (isopropyl alcohol). Resulting suspensions were dried onto a microscope cover glass, attached with carbon glue to an SEM stub, sputter coated with platinum, and examined with a Phillips XL20 SEM (Institute of Paleobiology, Warsaw) at magnifications from $\times 100$ to $\times 5,000$ and a voltage of 25 kV. Among the 48 examined samples, those from the interval 97.39 m in the core (71.23 m vertical equivalent depth) to 153.30 m in the core (112.12 m vertical depth) revealed abundant sponge spicules. The investigated material is curated in the collection of the Institute of Paleobiology, Polish Academy of Sciences, Warszawa, Poland, under the accession number ZPAL Pf. 23.

RESULTS

In a general sense, most of the samples rich in sponge spicules also contain diverse diatom (Bacillariophyceae), chrysophyte

(Chrysophyceae and Synurophyceae) and euglyphid (Euglyphidae, Rhizaria) assemblages, many of which retain pronounced affinities with modern taxa (Siver and Wolfe, 2005, 2009). Numerous morphotypes of birotule and non-birotule gemmuloscleres (spicules forming an armour of the resting bodies), as well as microscleres, were recognized, together representing a highly diversified assemblage of freshwater sponges.

The identification of freshwater sponges, as is the case with other siliceous sponge groups, is based on the character and organization of spicules, including megascleres, microscleres and gemmuloscleres. Megascleres are similar in many species of freshwater sponges, however gemmuloscleres are highly diagnostic at the species level, and isolated specimens can be used to identify specific taxa in a fossil sample even if the whole sponge is not preserved.

The Giraffe material contains a rich diversity of freshwater sponges with 14 or more species documented to date (Pisera et al., 2008; Pisera, 2010). The majority belongs to the family Spongillidae Gray 1867, including the cosmopolitan genus *Ephydatia*, and will be described in detail elsewhere. The present paper focuses on remains of spicules representing the family Potamolepidae Brien 1967 (Figs. 2, 3), including the description of a new species.

SYSTEMATIC PALEONTOLOGY

Class DEMOSPONGIAE Sollas, 1885
 Family POTAMOLEPIDAE Brien, 1967
 Genus POTAMOPHLOIOS Brien, 1970

Type species.—*Potamolepis stendelli* Jaffe, 1916.

Diagnosis.—After Manconi and Pronzato (2002), Potamolepidae with large body size (50–15 cm) ranging from encrusting to massive and lobate. Color from gray to dark gray. Consistency

FIGURE 2—*Patomophloios canadensis* n. sp., type material from 110.83 m depth in the Giraffe core, ZPAL Pf. 23/A395. Gemmulosclere strongyles.

hard. Surface irregular with conules. Ectosomal skeleton with tangential small oxeas. Choanosomal skeleton dense alveolate with a more open network in the basal portion. Megascleres stout smooth strongyles with inflated ends but also more slender strongyles are present. Microscleres oxeas as dermal spicules. Gemmules single or grouped, from subspherical to oval or hemispherical when strictly adhered to the substratum. Foramen primitive with a simple inconspicuous concavity. Theca monolayered of compact spongin. Gemmuloscleres smooth to spined, elongated to oval strongyles.

POTAMOPHLOIOS CANADENSIS new species

Figures 2, 3

Diagnosis.—*Patomophloios* characterized by gemmuloscleres that are smooth strongyles of small and highly variable shape and size, often bent, curved or irregular.

Description.—Material studied includes loose spicules on SEM stubs (ZPAL Pf.23/A105, A395). The spicules are smooth, thick, strongyles with highly variable dimensions (Figs. 2, 3). Spicules are often curved, bent, or otherwise slightly irregular. Many specimens have inflated tips. Their size range is from 7.90–30.9 µm long × 3.12–5.0 µm wide (Figs. 2, 3). We recognize, however,

FIGURE 3—*Patomophloios canadensis* n. sp. from 112.12 m depth in the Giraffe core, ZPAL Pf.23/A105. Gemmulosclere strongyles.

that similar large size differences also characterize modern potamolepid sponges (Manconi and Pronzato, 2010; Volkmer-Ribeiro et al., 2010). Microscleres are absent.

Etymology.—Referring to Canada, where the sponge was found.

Type specimens.—The collection of specimens on SEM stub A395 (collection number ZPAL Pf. 23/A395), here illustrated on Figure 2.

Occurrence.—Middle Eocene (Lutetian) lake sediments, Giraffe kimberlite maar, northern Canada, (64°44' N, 109°45' W).

Remarks.—Highly variable abundances of spicules attributed to potamolepid sponges were observed in the Giraffe Pipe core from vertical depths between 112.12 m and 76.93 m. The greatest concentrations occurred between 112.12 m and 101.10 m, and again at 76.93 m, close to the transition from aquatic to terrestrial environments, when the lake was shallowing.

Spicules of similar morphology to the smooth and thick strongyles observed in the Giraffe material occur not only in the family Potamolepididae, but also in other recent spongillids such as

the genus *Corvospongilla* Annandale, 1911 (Manconi and Pronzato, 2004, 2009; Ruengswang et al., 2012). For example, *C. mesopotamica* and *C. thysii* can have similar megascleres and gemmuloscleres but these species also produce oxea megasclere and microsclere spicules that were not observed in the Giraffe samples containing numerous gemmular strongyles. The species *Corvospongilla siamensis* Manconi and Ruengswang (Ruengswang et al., 2012) described from Thailand has gemmuloscleres of similar morphology but they are adorned with spines and never have inflated ends. This species is also characterized by micropseudobiotule microscleres.

Strongyles and oxea megascleres, which may represent megascleres of newly described species, occur in some samples higher up in the core. However, the sample from 110.83 m contains numerous small strongyles, interpreted as gemmuloscleres, and no other types of spicules. The fact that we observed only gemmuloscleres, and not megascleres in this sample (the most rich in the discussed spicules) may suggest selective transport of

various sponge components. On the other hand, the absence of any microscleres that are of similar size suggests that the investigated sponges lacked microscleres, which matches the characteristics of Potamolepidae. In fact, even if microscleres that belong to other genera occur in various samples higher up in the core, none of them can be attributed to the genus *Corvospongilla*. Thus, we conclude that the source organism was characterized by strongyles as gemmuloscleres, with no microscleres, consistent with our designation of a new species within the family Potamolepidae. Due to the fact that possible megascleres of this species occur in multispecific assemblage of spicules, their unequivocal attribution to this new species is not currently possible because similarly shaped megascleres may occur in other genera. The strongyle spicules observed in this study are very small, much more so than any observed in modern representatives of the family. The small size is unlikely attributable to low ambient silica concentrations, because the presence of primary opal-A nodules and significant concentrations of other siliceous microfossils suggest that silica concentrations were replete. Lastly, in cases when the strongyles co-occur with other sponge spicules, the latter show no evidence of size reduction. We conclude that the investigated spicules belong to a species in the genus *Potamophloios* (see Manconi and Pronzato, 2009; Volkmer-Ribeiro et al., 2010), but as noted they are smaller and always completely smooth compared to known species in the genus. Taking into account the size differences and morphological characters, as well as their Eocene age, we conclude that these spicules belong to a new species of the genus *Potamophloios* Brien, 1970, and not *Corvospongilla* Annandale, 1911.

DISCUSSION

To this point, the only known and therefore oldest fossil potamolepid sponge is *Oncosclera kaniensis* from what are likely early Miocene fluvial sediments from Japan (Matsuoka and Masuda, 2000). This and other occurrences have been cited as evidence for a Gondwanan origin of the family (Volkmer-Ribeiro and Rosa-Barbosa, 1978; Volkmer-Ribeiro, 2007; Erpenbeck et al., 2011). The findings reported here not only refute this notion but also extend the fossil record of Potamolepidae by approximately 20 million years, to at least the middle Eocene.

At present, representatives of the Potamolepidae occur only in Africa (four genera), the Neotropics (three genera), the Pacific Oceanic Islands (one genus) (Manconi and Pronzato, 2002), and Indochina (one genus) (Manconi et al., 2012). The family is thus strongly restricted to tropical climate regimes, with no known temperate, boreal, or polar occurrences (Manconi and Pronzato, 2002, 2009). The presence of potamolepid sponges near the Arctic Circle in northern Canada during the middle Eocene therefore confirms a near-tropical climate state during deposition of lake sediments in the Giraffe maar. This idea supports previous findings based on remains of tropical chrysophytes and diatoms (Siver and Wolfe, 2009) that co-occur with the potamolepid sponge spicules in these sediments, collectively indicating a warm, subtropical to tropical climate, with markedly reduced seasonality and the absence of frost.

As is true of most freshwater sponges, living potamolepid sponges are characteristic of lakes and rivers and require firm substrates, such as rocks, wood fragments or plants, for colonization (Frost et al., 2001; Manconi and Pronzato, 2002, 2009). Pinheiro (2007) reported that the potamolepid genera *Oncosclera*, *Sterrastolepis* and *Uruguayia* from Brazil required hard substrata, typically rock or concrete, and some *Oncosclera* species may grow on bamboo sticks (Manconi et al., 2012). One species, *Oncosclera spinifera*, inhabits very shallow (<20 cm

deep) water with temperature 30°C and pH=7. Numerous well-preserved spicules have been uncovered from the Giraffe core, but to date no whole intact gemmules have been found. Given that gemmules have a relatively high preservation potential (Pisera and Saez, 2003), it is possible that the sponges inhabited the rocky walls of the crater margin rather than the sediment surface itself, and that spicules were preferentially transported to the soft sediment as disarticulated elements, facilitated by the fact that the gemmular structure in potamolepids is based largely on siliceous spicules while spongin is very scanty (R. Manconi, personal commun.).

CONCLUSIONS

Middle Eocene lacustrine sediments from the Giraffe fossil locality are rich in siliceous microfossils with remarkable preservation, among them sponge spicules that we interpret as gemmuloscleres referable to the family Potamolepidae. Small and smooth strongyles were found throughout much of the core, with the highest concentrations near the top of the lacustrine facies that captures shallowing of the limnic environment prior to terrestrialization. Because modern potamolepid sponges have pronounced tropical affinities, these observations offer yet another bioindicator supporting the notion of biogeographic reorganizations during the warm climatic conditions that characterized northern Canada during the middle Eocene. This discovery further extends the known age range of the family Potamolepidae by ~20 Ma, which is directly relevant to better constraining the phylogeny of freshwater sponges as a whole.

ACKNOWLEDGMENTS

This study was financed by the Institute of Paleobiology, Polish Academy of Sciences, to A. Pisera, the National Science Foundation (grants DEB-0716606 and DEB-1144098) to P. Siver, and a Natural Sciences and Engineering Research Council of Canada Discovery Award to A. Wolfe. We would like to thank R. Manconi (Sassari) and M. Wuttke (Mainz) for critical remarks.
