Abstract

This note illustrates theoretical worst-case scenarios for groundness analyses obtained through abstract interpretation over the abstract domains of *definite* (Def) and *positive* (Pos) Boolean functions. For Def, an example is given for which any Def-based abstract interpretation for groundness analysis follows a chain which is exponential in the number of argument positions as well as in the number of clauses but sub-exponential in the size of the program. For Pos, we strengthen a previous result by illustrating an example for which any Pos-based abstract interpretation for groundness analysis follows a chain which is exponential in the size of the program. It remains an open problem to determine if the worst case for Def is really as bad as that for Pos.

1 Introduction

Boolean functions play an important role in various formal methods for specification, verification and analysis of software systems. In program analysis, Boolean functions are often used to approximate properties of the set of states encountered at a given program point. For example, a conjunction $x \wedge y$ could specify that variables x and y satisfy some property whenever control reaches a given program point. A Boolean function $\varphi_1 \rightarrow \varphi_2$ could specify that if φ_1 is satisfied at a program point (perhaps depending on the unknown inputs to the program) then also φ_2 is satisfied. A disjunction $\varphi_1 \vee \varphi_2$ could arise as a consequence of a branch in the control where φ_1 and φ_2 approximate properties of the `then` and `else` branches, respectively.

For program analysis using Boolean functions, we often consider the *positive* Boolean functions, Pos. Namely, those for which $f(1, \dots, 1) = 1$ (denoting *false* and *true* by 0 and 1 respectively). This restriction is natural as, due to the element of approximation, the result of an analysis is not a ‘yes/no’ answer, but rather a ‘yes/maybe not’ answer. In this case there is no ‘negative’ information. Sophisticated Pos-based analyzers implemented using binary decision diagrams (Bryant, 1992)

have been shown (Van Hentenryck *et al.*, 1995) to give good experimental results with regards to precision as well as the efficiency of the analyzers. However, scalability is a problem and inputs (programs) for which the analysis requires an exponential number of iterations or exponentially large data structures are encountered (Codish, 1999).

The domain, *Def*, of definite Boolean functions is a subdomain of *Pos*. These are the positive functions whose sets of models are closed under intersection. The domain *Def* is less expressive than *Pos*. For example, the formula $x \vee y$ is not in *Def*. However, *Def*-based analyzers can be implemented using less complex data structures and can be faster than *Pos*-based analyzers. For goal dependent groundness analyses (where a description of the inputs to the program being analyzed is given) *Def* has been shown to provide a reasonable tradeoff between efficiency and precision (King *et al.*, 1999; Howe & King, 2000).

The work described in Codish (1999) illustrates a series of pathological inputs for *Pos*-based groundness analysis. That paper defines a predicate $chain(x_1, \dots, x_n)$ using n clauses and illustrates that its *Pos*-based groundness analysis requires 2^n iterations. However, given that the size of the program (the total number of arguments), is quadratic in n ($m = n^2 + n$), the number of iterations is sub-exponential in the size of the input (2^n or $2^{O(\sqrt{m})}$). It has been suggested that *Def* analyses might provide better scalability properties than *Pos* due to the restriction to functions whose models are closed under intersection. This note makes two contributions:

1. It demonstrates that the worst-case behavior of a *Def*-based analysis is (at least) as bad as that described in Codish (1999) for *Pos*-based analyses; and
2. It demonstrates that the worst-case behavior of a *Pos*-based analysis is exponential in the size of the input.

We have not succeeded to demonstrate a worst-case analysis for *Def* for which the number of iterations is exponential in the size of the input, nor to prove that *Def*-based groundness analysis has sub-exponential worst-case behavior. This remains an open problem.

2 A potential worst-case for *Def*

Consider an n -ary Boolean function f . A model M of f can be viewed as a sequence (b_1, \dots, b_n) of zero's and one's such that $f(b_1, \dots, b_n) = 1$. For the sake of our construction, we order n -ary models according to their value as n -digit binary numbers. So a model M_1 is smaller or equal to a model M_2 if and only if the binary number corresponding to M_1 is less or equal to the binary number corresponding to M_2 . The intersection of models is defined as usual so that $(a_1, \dots, a_n) \cap (b_1, \dots, b_n) = (c_1, \dots, c_n)$ where $c_i = 1$ if and only if $a_i = b_i = 1$.

Let us first comment on the series of programs which demonstrates the potential worst-case behavior of a *Pos*-based groundness analysis (Codish, 1999). The analysis of the predicate $chain/n$ enumerates the models of the (constant) n -ary Boolean function 1 (*true*) in reverse order. Starting from the initial approximation (which has no models), each consecutive approximation is a function which has one new model that

was not in the previous iteration. For example, when $n = 3$, the models accumulate in the following order: $(1, 1, 1), (1, 1, 0), (1, 0, 1), (1, 0, 0), \dots, (0, 0, 0)$ and the Pos-based analysis totals 8 iterations. In contrast the corresponding Def-based analysis totals 4 iterations because at each iteration the current set of models is closed under intersection. So for example, in the third iteration, the set $\{(1, 1, 1), (1, 1, 0), (1, 0, 1)\}$ is closed to give $\{(1, 1, 1), (1, 1, 0), (1, 0, 1), (1, 0, 0)\}$.

We now construct a series of programs which demonstrates the potential worst-case behavior of a Def-based groundness analysis. This construction is based on the following observation:

Proposition 2.1

Let M be an n -ary model. Then the set of n -ary models smaller or equal to M is closed under intersection.

Proof

The result follows from the following observation: If M_1 and M_2 are n -ary models, then $M_1 \cap M_2$ is no larger than M_1 (and no larger than M_2). This is because $M_1 \cap M_2$ is obtained from M_1 (or from M_2) by changing some one's to zero's. \square

A consequence of Proposition 2.1 is that the domain of definite Boolean functions over n variables contains a chain of length 2^n . To demonstrate such a chain consider an enumeration M_0, \dots, M_{2^n-1} of the n -ary models according to their binary ordering (so $M_0 = (0, \dots, 0)$ and $M_{2^n-1} = (1, \dots, 1)$). Observe that M_i is the n -ary binary representation of i . Define a sequence $F = (f_0, \dots, f_{2^n-1})$ as follows: let f_0 be the Boolean function with the empty set of models and for $0 < i < 2^n - 1$ define f_i to be the Boolean function whose models are $\{M_0, \dots, M_{i-1}\} \cup \{M_{2^n-1}\}$. From the construction it is clear that F forms a chain. Moreover, the elements of F are in Def: They are positive because they have M_{2^n-1} as a model; and from Proposition 2.1, it follows that they are closed under intersection. The chain F is of length $2^n - 1$ because, for $1 < i < 2^n - 1$ f_i has exactly one model more than f_{i-1} . This is the setting for our construction.

The (Def-based) groundness analysis of the following predicate ‘ p/n ’ iterates through the chain F . The arguments typeset in boldface highlight the case for $n = 4$. The program size is quadratic in n and consists of a single predicate of arity n with $n + 1$ binary clauses. The analysis of the program can be viewed as counting from zero to $2^n - 2$ in its arguments.

$$\begin{array}{l}
 p(X_n, \dots, \mathbf{X_4, X_3, X_2}, \mathbf{c}) \leftarrow p(X_n, \dots, \mathbf{X_4, X_3, X_2}, \mathbf{X_1}). \\
 p(X_{n-1}, \dots, \mathbf{X_3, X_2, c}, \mathbf{X_1}) \leftarrow p(X_{n-1}, \dots, \mathbf{X_3, X_2}, \mathbf{X_1}, \mathbf{c}). \\
 p(X_{n-2}, \dots, \mathbf{X_2, c, X_1}, \mathbf{X_1}) \leftarrow p(X_{n-2}, \dots, \mathbf{X_2, X_1}, \mathbf{c}, \mathbf{c}). \\
 \vdots \\
 p(\mathbf{c}, \mathbf{X_1}, \dots, \mathbf{X_1}, \mathbf{X_1}) \leftarrow p(\mathbf{X_1}, \mathbf{c}, \dots, \mathbf{c}, \mathbf{c}). \\
 p(\mathbf{X_1}, \mathbf{X_1}, \dots, \mathbf{X_1}, \mathbf{X_1}).
 \end{array}$$

3 A challenge

The Def- and Pos-based groundness analyses of the predicate p/n program in the series given in this note involve an exponential number of iterations and compute an n -ary Boolean function. The same is true for the Pos-based analysis of the series given in Codish (1999). However, it is important to note that complexity is typically expressed in terms of the size of the input to a problem and that the size of the program defining p/n in both series is quadratic in n ($m = n^2 + n$). Hence, formally speaking, we have shown that both Def and Pos-based groundness analyses may potentially involve a number of iterations which is $2^{O(\sqrt{m})}$. This is bad enough, but sub-exponential.

For Pos, we can strengthen the result. The following program is of size linear in n ($m = 11 \cdot n$) and its Pos-based groundness analysis requires $2^n - 2$ iterations.

$$\begin{aligned} & p(X_1, \dots, X_1). \\ & p(A_1, \dots, A_n) \leftarrow p(B_1, \dots, B_n), s(A_1, \dots, A_n, B_1, \dots, B_n). \\ & s(c, X_1, \dots, X_1, X_1, c, \dots, c). \\ & s(W, A_1, \dots, A_{n-1}, W, B_1, \dots, B_{n-1}) \leftarrow s(A_1, \dots, A_n, B_1, \dots, B_n). \end{aligned}$$

Intuitively, the $2n$ arguments of the predicate $s/2n$ represent two n -digit binary numbers (the first is the successor of the second) so that the n recursive clauses from the program in Section 2 can be simulated by two clauses for $s/2n$. The base case of $s/2n$ corresponds to the last recursive clause. However, the analysis of $s/2n$ does not follow an exponential chain so we still need the predicate p/n to get the worst-case behaviour. This approach does not work for Def because the result in Pos for $s/2n$ is not closed under intersection.

4 Conclusion

We have demonstrated a $2^{O(m)}$ worst case complexity for Pos and at least $2^{O(\sqrt{m})}$ for Def (where m is the size of the program). It remains to be determined if the worst case for Def is really as bad as that for Pos or perhaps Def has better worst-case behaviour.

Theorem 4.1

Groundness analysis using Def has a potential worst-case behaviour involving $2^{O(\sqrt{m})}$ iterations, where m is the size of the program.

Theorem 4.2

Groundness analysis using Pos has a worst-case behaviour involving $2^{O(m)}$ iterations, where m is the size of the program.
