

Cytomegalovirus ulceration of the oropharynx

P. D. FRENCH, M.R.C.P., M. A. BIRCHALL, F.R.C.S., J. R. W. HARRIS, F.R.C.P. (London)

Abstract

Cytomegalovirus (CMV) is a common opportunistic infection in both iatrogenic and HIV-induced immunosuppression. The usual sites of involvement are the gastro-intestinal tract, retina and lung. We present three cases of CMV ulceration of the oropharynx. All three patients presented with symptoms localized to the oropharynx and in each case the diagnosis was only made on histological examination of ulcer biopsy specimens. The patients all responded well to ganciclovir treatment and at writing none have required maintenance therapy (7–11 months post diagnosis).

Case 1

A 27-year-old homosexual man with the acquired immunodeficiency syndrome (AIDS) was admitted to hospital in October 1989 with a six-week history of proximal odynophagia, right-sided sore throat and 3 kg weight loss. A right tonsillar fossa ulcer had been noted four weeks earlier in the out-patient clinic and swabs taken at this time for bacterial and *Herpes simplex* culture were negative. He was treated empirically for oral herpes simplex with acyclovir 200 mg five times per day for two weeks, with no response.

He was diagnosed human immunodeficiency virus (HIV1) antibody positive in February 1988. He had latent syphilis treated in 1983 and suffered from recurrent perianal *Herpes simplex*. In September 1988 he was treated for *Pneumocystis carinii* pneumonia (PCP) after which he remained symptomless (apart from occasional perianal herpes) until the onset of dysphagia.

Since the PCP he had been taking dapsone 100 mg/pyrimethamine 25 mg weekly (as PCP prophylaxis) and zidovudine 200 mg qds. He had been taking acyclovir 200 mg twice daily for six months as successful perianal herpes prophylaxis and was also taking fluconazole 50 mg daily for oral candida.

Examination revealed a shallow ulcer (0.3 cm × 0.5 cm) centred on the tonsil and anterior pillar of the fauces with yellow slough at its base and a surrounding raised erythematous area (Fig. 1). There were no other oropharyngeal ulcers and ENT examination including indirect laryngoscopy was normal. General examination including fundoscopy was unremarkable apart from a low grade pyrexia (37.4C).

Biopsy of the ulcer revealed an acute inflammatory response with typical CMV inclusion bodies in the cells of the endothelium (Fig. 2).

He was treated with ganciclovir (dihydroxyprproxy-methyl guanine; DHPG) 300 mg per day intravenously for two weeks which resulted in complete resolution of

the ulcer. In the 11 months following this episode he has not required DHPG maintenance therapy.

Case 2

A 43-year-old homosexual man with AIDS presented in March 1990 with an 8 week history of odynophagia and weight loss of 6 kg. On indirect laryngoscopy a round, 1 cm diameter, yellow-based ulcer with raised edges and a base of slough in the left vallecula and ulceration involving much of the ventral epiglottis was noted.

Swabs taken for bacterial and *Herpes simplex* culture were negative.

He was diagnosed HIV1 antibody positive in November 1988. He had secondary syphilis treated in 1979 and had single dermatomal *Herpes zoster* in 1982. He devel-

Case 1 showing an ulcer on the tonsil and anterior pillar of the fauces.

FIG. 2

Photomicrographs of tonsillar biopsy from case 1. Low power picture shows extensive polymorphonuclear cell infiltrate (a; $\times 40$), while higher power reveals endothelial cell swelling and prominent CMV inclusion body (b; $\times 1000$).

FIG. 3

Case 3 showing linear deep palatal ulceration.

oped PCP in February 1989 and lingual herpes simplex infection in March 1989 both of which responded to treatment. He later developed two lesions of Kaposi's sarcoma on his right upper arm.

His medication on admission included zidovudine 250 mg qds which he had been taking since he developed PCP, ketoconazole 200 mg od as oral candida prophylaxis and acyclovir 200 mg \times 5/day for the preceding two weeks to which his ulcer had not responded.

Examination (including fundoscopy) was unremarkable apart from the above Kaposi's sarcoma lesions. To establish a histological diagnosis, direct laryngoscopy under general anaesthesia was performed and revealed the ulcer to be a similar size to the previous examination but now with extensive erosion of the epiglottic cartilage and consequent chondritis. A biopsy of the ulcer revealed typical CMV inclusion bodies in the endothelium.

He was treated with DHPG 300 mg daily intravenously for two weeks which resulted in complete resolution of his dysphagia. Indirect laryngoscopy performed one month after treatment revealed the epiglottis had re-epithelialized. He remains well seven months later and has not required DHPG maintenance therapy.

Case 3

A 56-year-old renal transplant recipient was transferred to this unit for assessment in October 1989. He gave a two-week history of hoarseness, sore throat and mouth ulceration.

He gave a past history of hypertension and chronic renal failure and had undergone renal transplantation in 1987. This had been rejected and he had a second renal transplant in February 1989. Apart from his antihypertensive medication, he was receiving prednisolone 17.5 mg daily, cyclosporin 300 mg daily and azathioprine 500 mg daily. A week before transfer he was commenced on empirical therapy for oral *Candida* and *Herpes simplex* with fluconazole 100 mg orally daily and acyclovir 250 mg intravenously daily respectively with no relief of symptoms.

Examination revealed him to be anaemic and to have a peritoneal dialysis catheter *in situ*. He had severe bullae formation and ulceration of the palate and oropharynx.

Direct laryngoscopy was performed under general anaesthesia. Two linear ulcers on the palate were noted (Fig. 3) as well as a swollen supraglottis with tiny superficial bullae. Biopsies from the palate, supraglottis and ventral epiglottis all revealed numerous intranuclear and intracytoplasmic inclusions consistent with CMV.

He was treated with DHPG 300 mg daily intravenously for two weeks with symptomatic improvement. When reviewed one week into his DHPG treatment by indirect laryngoscopy his palatal ulcers were healing and the supraglottis was erythematous but less swollen. Ten months later he has had no recrudescence of his symptoms.

Discussion

Cytomegalovirus is a member of the herpes family of viruses and like other herpes viruses produces latent infection. Between 50 and 80 per cent of the adult population of the UK and nearly 100 per cent of HIV antibody positive homosexual men are infected with cytomegalovirus. However, serious disease associated with cytomegalovirus in adults is confined to those with immunosuppression. It is an important pathogen in both HIV-related and iatrogenic immunosuppression (Peterson, R. K., *et al.*, 1980; Pinching, 1989). Although the most common clinical manifestations of CMV are in the retina, lung and gastrointestinal tract, a literature search reveals five case reports of CMV-associated ulceration of the oropharynx (Williams *et al.*, 1960; Robson and Mackay, 1969; Takagi and Ishikawi, 1977; Myerson, D. *et al.*, 1984; Kanas *et al.*, 1987).

In HIV infection, CMV-related oropharyngeal ulceration has been described as the index diagnosis of AIDS (Kanas *et al.*, 1987) and CMV has been implicated as a cause of recurrent laryngeal nerve palsy (Small *et al.*, 1989). Williams *et al.* describe a 25-year-old man with CMV mucosal ulceration and *Pneumocystis carinii* pneumonia with no obvious underlying cause although recently a retrospective diagnosis of HIV infection has been made (Williams *et al.*, 1960; Corbitt *et al.*, 1990). CMV ulceration of the oropharynx has also been associated with patients receiving immunosuppressive therapy for lupoid hepatitis (Robson and Mackay, 1969) and bone marrow transplantation (Myerson *et al.*, 1984) as well as a patient receiving chemotherapy for renal carcinoma (Takagi and Ishikawi, 1977). In only one of these patients was the diagnosis made ante mortem (Kanas *et al.*, 1987).

Effective therapy for CMV now exists although both available drugs, DHPG and foscarnet, have significant toxicity (myelotoxicity and nephrotoxicity particularly respectively). There are many causes of oropharyngeal ulceration in immunocompromised patients and, as our cases show, CMV can present with a confusing variety of macroscopic appearances. Therefore it is vital to make a histological diagnosis. In the oropharynx, this is best achieved under general anaesthesia with good lighting and suction. It is important when undertaking this procedure to remember that this group of patients may have clotting disorders such as thrombocytopenia that might require pre-operative treatment. The differential diagnosis includes infections such as *Herpes simplex* (Cohen and Greenberg, 1985), *Candida* and, particularly in HIV

infection, aphthous ulceration and secondary tumours such as Kaposi's sarcoma and lymphoma.

Most patients with AIDS and pathogenic CMV infection relapse after discontinuing DHPG (Jeffries, 1989). Relapse of CMV in patients with retinitis can lead to permanent visual loss and it is not therefore justified to withhold maintenance DHPG. However with the oropharyngeal ulceration of our patients, the role of maintenance DHPG is uncertain and is possibly only needed if relapse occurs. Patients with transient iatrogenic immunosuppression such as Case 3 do not usually require maintenance therapy.

In summary, CMV induced ulceration of the oropharynx is a treatable condition with significant morbidity if not diagnosed early. Biopsies of all oropharyngeal ulcers in immunocompromised patients should be taken in those who fail to respond to simple non-toxic medication.
