Abstract

In the Late Neoproterozoic, the lithosphere of the North China Craton (NCC) experienced a strong extensional event, which is of great significance for understanding the evolution of the continental crust in the Precambrian. In this study, a suite of mafic dykes from Shandong province in the northeastern NCC were investigated to determine the nature, timing and source of rift-related magma activities using zircon U–Pb data, whole-rock geochemistry and Nd–Hf isotopes. Zircon U–Pb dating of four dolerites by laser ablation – inductively coupled plasma – mass spectrometry (LA-ICP-MS) yielded weighted mean ²⁰⁷Pb/²⁰⁶Pb ages in the range 2509 ± 6.1 to 2537 ± 6.2 Ma (2σ, 95 % confidence interval). The mafic dykes are classified as alkaline rocks based on their K₂O + Na₂O contents (6.78–7.21 wt %) and belong to the shoshonitic series according to their K₂O contents (3.23–3.36 wt %). The dolerites show low concentrations of light rare earth elements ((La/Yb)_N between 7.17 and 8.55), positive Eu anomalies (Eu/Eu* between 1.12 and 1.27), positive Ba, K, Pb, Sr, Eu, Dy and Lu anomalies, and depleted U, Nb, Pr, Ta, P, Nd and Ti anomalies. The dykes are characterized by low initial (⁸⁷Sr/⁸⁶Sr)_i (~0.6969), positive ε_{Nd}(*t*) values (0.2–0.8) and ε_{Hf}(*t*) values (0.5–8.6) and relatively old mean Nd and Hf model age (2.73 Ga). Collectively, the data suggest that the mafic dykes were derived from the partial melting (10–20 %) of an isotope-depleted garnet–lherzolite mantle source that was hybridized through interaction with subducted lower crustal material. The parental magmas of these dykes underwent a certain number of crustal contaminations during magma ascent. The mafic magmatism represented in the form of the dyke swarms is considered to be a response to widespread lithospheric extension which affected the NCC at *c.* 2.5 Ga during the Neoproterozoic.

1. Introduction

The North China Craton (NCC) was formed by welding several Archaean micro-continents along a marine closed greenstone belt (Zhai & Santosh, 2011; Yang *et al.* 2016; Tang & Santosh, 2017; Yang & Santosh, 2017). A large number of ~2.5 Ga rock units were preserved in the NCC (Wu *et al.* 1998; Zhai & Bian, 2000; Zhai, 2010). The NCC covers a vast area of eastern China (Wu *et al.* 2008), which includes two ancient continental cores of *c.* 3.8 Ga age (Jahn & Bai, 1983; Huang *et al.* 1986; Liu, 1991; Liu *et al.* 1992, 1994; Song *et al.* 1996; LQ Wang *et al.* 1998; Zheng *et al.* 2004; Gao *et al.* 2005; Shen *et al.* 2005; Wan *et al.* 2005; Geng *et al.* 2007; HL Wang *et al.* 2007; Diwu *et al.* 2008; Chen *et al.* 2009; Zhang *et al.* 2009). The NCC was finally cratonized in the Late Palaeoproterozoic, thus recording a complex Precambrian evolution history. All crustal fragments gathered in the unified NCC were merged into the Columbia supercontinent (Santosh, 2010; Zhao & Zhai, 2013). In addition, the NCC underwent an extensional regime between 2.5 and 2.45 Ga (Zhai & Peng, 2007), leading to basement uplift, formation of rift-related troughs, and major anorogenic magmatism represented by the emplacement of granitoid suites (e.g. Song *et al.* 1996) and mafic dykes. The events related to the emplacement of the mafic dykes can provide important information about the formation and evolution of the early crust. To date, more than 100 Proterozoic (<2.5 Ga) mafic dykes have been found in the NCC including those in the Hebei, Shanxi and Shandong area with ages ranging from 800 to 600 Ma, 820 Ma, 900 Ma, 925 Ma, 1.78 Ga and 2.4 to 1.6 Ga. They have been widely studied (Li *et al.* 1997; Zhai & Bian, 2000; Peng *et al.* 2005, 2007, 2008, 2010, 2011a, b; Hou *et al.* 2006; Peng, 2010; Hou, 2012; Li, 2014). Nevertheless, only a few investigations of the Archaean mafic dykes (>2.5 Ga) have been carried out in the NCC.

At present, the western part of Shandong province has been the focus of several studies related to the Early Precambrian evolutionary history of the NCC (Hou, 2012). Approximately 95 % of the Early Precambrian crystalline basement in western Shandong is

dominated by granulites, greenstones, Trondhjemite-Tonalite-Granodiorite (TTG) gneisses, gneissic monzogranite, dioritic to granodioritic intrusions, and mafic dyke swarms (Wang, 1990; Hou *et al.* 2004; Ju *et al.* 2014). In addition, the TTG series rocks and gneissic monzogranites in this area have been divided into two stages (2.5–2.6 Ga, 2.45–2.56 Ga; Jahn, 1988; Wang, 1991, 1993). The mafic dykes in western Shandong province are generally NE–SW-trending and are mainly located in the Tai'an, Laiwu and Mengyin regions (Hou, 2012).

Herein, we present new zircon $^{207}\text{Pb}/^{206}\text{Pb}$ ages, and petrological, whole-rock geochemical and Nd–Hf isotopic data on the mafic dykes studied from western Shandong province, northeastern NCC. Our results constrain the emplacement ages and the origin of the dykes and provide insights into the tectonic significance of the NCC during the Neoproterozoic.

2. Geological setting and petrography

As a part of the Sino-Korean Craton, the Precambrian crustal evolution history of the NCC and the extensive Mesozoic redemption events have attracted global attention (Griffin, 1992; Griffin *et al.* 1998; O'Reilly *et al.* 2001; Xu, 2001; Zhang *et al.* 2003; Zhai & Santosh, 2011, 2013; Zhao & Zhai, 2013; Deng *et al.* 2017; Li & Santosh, 2017). The NCC is bounded by the Early Palaeozoic Qilianshan Orogen to the west, the Late Palaeozoic Tianshan – Inner Mongolia – Daxinganling Orogen of the Central Asian Orogenic Belt to the north and the Mesozoic Qinling–Dabie–Sulu high/ultrahigh-pressure metamorphic belt to the south (Zhao, 2013).

According to the structural subdivision view of the NCC, it is composed of two north–south-trending Palaeoproterozoic (1.85 Ga) eastern and western crustal blocks welded across the North China Orogenic Belt (Zhao *et al.* 2001, 2005; Wilde *et al.* 2002; Guo *et al.* 2005). The Eastern Block experienced obvious lithospheric thinning in the Late Mesozoic, and it contains many world-class gold deposits (Goldfarb & Santosh, 2014; Li & Santosh, 2017). It separates the Longgang Block from the Langlin Block and retains the oldest continental crust of the NCC (Fig. 1; Li *et al.* 2006, 2012; Li & Zhao, 2007; Luo *et al.* 2008; Zhou *et al.* 2008; Tam *et al.* 2011, 2012a, b, c; Dan *et al.* 2012, 2014; Zhang *et al.* 2013). The Western Block has thick lithospheric roots across Shanxi, Shaanxi, Inner Mongolia and Northern Gansu provinces. It has become the most stable part of the NCC (Santosh, 2010). It is a collage of the Northern Yinshan and Southern Ordos Blocks along the Inner Mongolia Suture Zone, merging the Palaeoproterozoic Khondalite Belt (Fig. 1; Xia *et al.* 2008; Yin *et al.* 2009, 2011; Santosh, 2010; Li *et al.* 2011; Wang *et al.* 2011; Dan *et al.* 2012, 2014; Zhang *et al.* 2013; Yang *et al.* 2016). The southern and northern edges of the NCC are marked by the Indosinian Qinling Dabie and Hercynian Yinshan Yanshan Orogenic Belts. Its western edge borders Helan Qilian Orogenic Belt, and its eastern edge is located in Korea. The NCC is composed of uniform Precambrian crystalline basement, which is covered by younger overburden (Zhao *et al.* 2001) and invaded by the Precambrian and Mesozoic mafic dyke swarms (e.g. Li *et al.* 1997; Zhai and Bian, 2000; Hou *et al.* 2004, 2006; Liu *et al.* 2004, 2005, 2008a, b, 2009, 2012a, b, 2013b; Peng *et al.* 2005, 2007, 2008, 2010, 2011a, b; Peng, 2010; Hou, 2012). Another model suggests that the NCC is composed of several Archaean micro-continental blocks and these blocks have been proliferated into large continental fragments (Zhai & Bian, 2000; Zhao, 2009; Zhai & Santosh, 2011;

Dan *et al.* 2012, 2014; Zhang *et al.* 2013; Yang *et al.* 2016; Yang & Santosh, 2017).

The fresh near-vertical mafic dykes in the study area are NE–SW-trending and intruded into luxiwu well in northeast North Carolina. The Early and Middle Proterozoic strata in the Mawangyu and Zhujiayu areas (Tables 1–5) have dykes extending from 3.0 to 9.0 km and a width range of 25–1.0 m. The rock types include gabbro, dolerite and diabase porphyry. Wujing dykes phenocrysts (WJA1–8, WJB1–8) include medium-grained clinopyroxene (2.5–6.5 mm) and tabular plagioclase (2.0–5.5 mm), and the matrix is composed of clinopyroxene (0.04–0.05 mm), plagioclase (0.03–0.06 mm), a small amount of magnetite (0.02–0.03 mm), secondary chlorite (0.03–0.05 mm) and auxiliary zircon composition (Fig. 1). The dyke phenocrysts of Mawangyu and Zhujiayu (MWY1–7, ZJY1–7) include medium-sized clinopyroxene (2.5–5.0 mm) and tabular plagioclase (2.0–5.0 mm), and the matrix consists of clinopyroxene (0.04–0.06 mm), plagioclase (0.03–0.05 mm), secondary magnetite with auxiliary zircon and apatite (0.02–0.03 mm) and secondary chlorite (0.04–0.06 mm) (Figs 1, 2).

3. Sampling and analytical techniques

Thirty samples were collected from the mafic dykes (Fig. 1). Zircon grains were separated from four samples (WJA1, WJB3, MWY2 and ZJY1) using conventional heavy liquid and magnetic techniques at the Langfang Regional Geological Survey, Hebei province, China. After separation and mounting, the morphology and internal structure of the zircons were imaged using transmitted and reflected light and by cathodoluminescence (CL) techniques at the State Key Laboratory of Continental Dynamics (SKLCD), Northwest University, Xi'an (Fig. 3). Prior to zircon U–Pb dating, grain mount surfaces were washed in dilute HNO_3 and pure alcohol to remove any potential lead contamination. Zircon U–Pb and $^{207}\text{Pb}/^{206}\text{Pb}$ weighted average ages were determined by LA-ICP-MS (Table 1; Fig. 4) using an Agilent 7500a ICP-MS instrument equipped with a 193 nm excimer laser at the SKLCD. The zircon standard 91500 was used for quality control, and a NIST 610 standard was used for data optimization. A spot diameter of 24 μm was used during analysis, employing the methodologies described by Liu *et al.* (2010a). Common Pb correction was undertaken following the approach of Andersen (2002), and the resulting data were processed using GLITTER and ISOPLOT (Ludwig, 2003; Table 1; Fig. 4). Uncertainties on individual LA-ICP-MS analyses are quoted at the 95 % (1σ) confidence level.

In situ zircon Hf isotope analysis was performed on Nu plasma Human Resource (HR) MC-ICP-MS equipped with a geolas 2005 193 nm ArF excimer laser ablation system. Analyses were carried out using a spot size of 44 μm , and He was used as the carrier gas. The laser repetition rate is 10 Hz and the energy density applied is between 15 and 20 J cm^{-2} . During the analysis, the $^{176}\text{Hf}/^{177}\text{Hf}$ ratio of the standard zircon (91500) was 0.282295 ± 0.000027 ($n = 14$; 2σ), which is in good agreement with the recommended $^{176}\text{Hf}/^{177}\text{Hf}$ ratios within 2σ (0.282308 ± 58 , 2σ ; 0.282015 ± 0.000029 , 2σ) (Griffin *et al.* 2006; Wu *et al.* 2006). All the above analysis was performed at the SKLCD.

Whole-rock chemistry was completed at the State Key Laboratory of Deposit Geochemistry (SKLDG, Xi'an, Shaanxi Province), Institute of Geochemistry, Chinese Academy of Sciences. Using a molten glass disc, the analytical accuracy was better than 5 % according to Chinese national standard GSR-3 (Table 2). Loss on ignition was obtained using 1 g powder heated

up to 1100 °C for 1 h. Trace element analysis was performed with an ELAN 6000 ICP-MS at the SKLDG, following procedures described by Qi *et al.* (2000). The discrepancy between triplicate analyses is less than 5 % for all elements. Analyses of international standards OU-6 and GBPG-1 are in good agreement with recommended values (Table 3). During Rb–Sr and Sm–Nd isotopic analysis, the sample powder was added with mixed isotopic tracer and dissolved in a polytetrafluoroethylene capsule with HF + HNO₃ (Zhang *et al.* 2001). Isotopic measurements were performed using a Finnigan Triton Ti thermal ionization mass spectrometer at the SKLDG. Procedural blanks yielded concentrations of <200 pg for Sm and Nd and <500 pg for Rb and Sr, and mass

fractionation corrections for Sr–Nd isotopic ratios were based on ⁸⁶Sr/⁸⁸Sr = 0.1194 and ¹⁴⁶Nd/¹⁴⁴Nd = 0.7219, respectively. Analysis of the NBS987 and La Jolla standards yielded values of ⁸⁷Sr/⁸⁶Sr = 0.710246 ± 16 (2σ), and ¹⁴³Nd/¹⁴⁴Nd = 0.511863 ± 8 (2σ), respectively.

4. Results

4.a. Zircon U–Pb ages

Euhedral zircons in samples WJA1, WJB3, MWY2 and ZJY1 are clean and prismatic and show clear oscillatory magmatic zoning

Table 2. Major element concentrations (wt %) for the mafic dykes studied. LOI = loss on ignition; Mg[#] = 100Mg/(Mg + Fe) in atomic proportions; RV = recommended values; MV=measured values. Values for GSR-1 and GSR-3 are from Wang *et al.* (2003)

(Fig. 3). Twenty-three zircon grains from sample WJA1 yielded a weighted mean ²⁰⁶Pb/²³⁸U age of 2523 ± 7.7 Ma (1σ, 95 % confidence interval; Table 1; Fig. 4a) and weighted mean ²⁰⁷Pb/²⁰⁶Pb age of 2538 ± 3.2 Ma (2σ, 95 % confidence interval; Table 1; Fig. 4e). Twenty-five zircon grains from sample WJB3 yielded a weighted mean ²⁰⁶Pb/²³⁸U age of 2509 ± 7.7 Ma (1σ, 95 % confidence interval; Table 1; Fig. 4b), and weighted mean ²⁰⁷Pb/²⁰⁶Pb age of 2510 ± 6.1 Ma (2σ, 95 % confidence interval; Table 1; Fig. 4f). Twenty-five zircon grains from sample MWY2 yielded a weighted

mean ²⁰⁶Pb/²³⁸U age of 2512 ± 12 Ma (1σ, 95 % confidence interval; Table 1; Fig. 4c) and weighted mean ²⁰⁷Pb/²⁰⁶Pb age of 2509 ± 6.2 Ma (2σ, 95 % confidence interval; Table 1; Fig. 4g). Twenty-four zircon grains from sample ZJY1 yielded a weighted mean ²⁰⁶Pb/²³⁸U age of 2539 ± 6.5 Ma (1σ, 95 % confidence interval; Table 1; Fig. 4d) and weighted mean ²⁰⁷Pb/²⁰⁶Pb age of 2537 ± 6.2 Ma (2σ, 95 % confidence interval; Table 1; Fig. 4h). These age data provide the best estimates of the crystallization ages of dykes (²⁰⁷Pb/²⁰⁶Pb weighted average *c.* 2.5 Ga) within the study

Table 3. Trace element compositions (ppm) of the mafic dykes studied. RV = recommended values; MV = measured values. Values for GBPG-1 and OU-6 are from Thompson *et al.* (2000) and Potts and Kane (2005), respectively.

area. No major zircon inheritance was observed in any of the samples.

4.b. Major and trace element geochemistry

The dykes studied appear quite evolved and show SiO_2 (52.11–52.36 wt %), TiO_2 (0.26–0.37 wt %), Al_2O_3 (20.25–20.68 wt %), Fe_2O_3 (8.34–8.86 wt %), MnO (0.18–0.26 wt %), MgO (4.03–4.38 wt %), CaO (5.52–5.76 wt %), Na_2O (3.55–3.93 wt %), K_2O (3.23–3.36 wt %) and P_2O_5 (0.25–0.38 wt %) (Table 2). All the dykes studied are classified as alkaline (shoshonites) on the total-alkali silica diagram (Figs. 5a and 6) and as shoshonites in a Na_2O vs K_2O diagram (Figs. 5b and 6). They are characterized by enrichment in $(\text{La}/\text{Sm})_{\text{N}}$ (1.57–2.57) and depletion in $(\text{Dy}/\text{Yb})_{\text{N}}$ (1.30–1.42), with a variation range in $(\text{La}/\text{Yb})_{\text{N}}$ (7.17–8.55), and the Eu/Eu^* ratios appears slightly positive (1.12–1.27) (Table 3; Figs. 7 and 8a, b, modified based on comments). Furthermore, the mafic dykes are enriched in Ba, K, Pb, Sr, Eu, Dy and Lu; with negative U, Nb, Ta, Pr, P, Nd and Ti anomalies in primitive-mantle-normalized multi-element variation diagrams (Figs. 7 and 8a, b).

4.c. Whole-rock Sr–Nd and zircon Hf isotopes

The Sr–Nd isotopic compositions of 16 representative dykes were determined (Table 4; Fig. 9). They have a relatively narrow range of $(^{87}\text{Sr}/^{86}\text{Sr})_{\text{i}}$ ratios (~0.6969) and have positive $\epsilon_{\text{Nd}}(t)$ values (0.2–0.8), implying an isotope-depleted magma source. The mean Nd model age is 2.73 Ga (DePaolo, 1981). The initial isotopic values of Sr are lower than those of BABI (Basaltic Achondrite Best Initial) (0.69899), for two main reasons (1) at least two mantle end elements (depleted mantle and enriched mantle) are involved

in the genetic process (Zhou & Armstrong, 1982; Zhi, 1990; Zou *et al.*, 2000); (2) high melting depth, homogeneity of source area and difference in lithosphere thickness (Niu *et al.*, 2011; Ye *et al.*, 2015). The Hf isotopic compositions of zircon from the mafic dykes were also determined (Table 5; Fig. 10). Twenty spot analyses were obtained for sample WJA1, yielding $\epsilon_{\text{Hf}}(t)$ values (–2.8 to 4.8) corresponding to T_{DM1} model ages (2.98–2.65 Ga, mean $T_{\text{DM1}} = 2.75$ Ga). Eighteen spot analyses were obtained for sample WJB3, and the results show $\epsilon_{\text{Hf}}(t)$ values (–0.5 to 5.5) corresponding to T_{DM1} model ages (2.8–2.61 Ga, mean $T_{\text{DM1}} = 2.73$ Ga). Eighteen spot analyses were obtained for sample MWY2, yielding a range of $\epsilon_{\text{Hf}}(t)$ values (–1.7 to 8.6) corresponding to T_{DM1} model ages (2.88–2.49 Ga, mean $T_{\text{DM1}} = 2.70$ Ga). Eighteen spot analyses in zircon grains from sample ZJY2 show $\epsilon_{\text{Hf}}(t)$ values (–1.4 to 8.2) corresponding to T_{DM1} model ages (2.9–2.53 Ga, mean $T_{\text{DM1}} = 2.71$ Ga). The mean T_{DM1} of the four zircons is 2.73 Ga, which is similar to the Nd model age.

5. Discussion

Based on zircon geochronology, whole-rock geochemistry and Nd–Hf isotopic evidence, this study reasonably limits the source area of mafic dykes, crustal contamination, fractional crystallization and magmatic evolution.

5.a. Mantle source and the origin

The mafic dykes studied are quite evolved, and the SiO_2 content is quite high (52.11–52.36 wt %; Table 2), implying an ultra-basic source for these rocks. An ultra-basic source is also supported by the relatively high $\text{Mg}^{\#}$ values (52–56; Table 1). It is unlikely that

Fig. 2. (Colour online) The field and microscopic photos of the mafic dykes studied. PI – plagioclase; Cpx – clinopyroxene.

the magma that formed these dykes had any contribution from crustal rocks (Hirajima *et al.* 1990; Zhang *et al.* 1995; Kato *et al.* 1997; Rapp *et al.* 2003), as lower crustal intermediate granulites (Gao *et al.* 1998a, b) would produce high-Si and low-Mg[#] melts. Moreover, the Zr/Nb (10–16) and Rb/Sr ratios (0.04–0.20) of the dykes studied (Table 3) suggest magma derivation from a depleted mantle source (Weaver, 1991). The dykes also show positive but variable $\epsilon_{\text{Nd}}(t)$ (0.2–0.8; Table 4) and $\epsilon_{\text{Hf}}(t)$ values (0.5–8.6), both of which are consistent with derivation from an isotope-depleted mantle (Liu *et al.* 2009). In addition to the evidence outlined above, plots La/Sm vs La, and Sm/Yb vs Sm (Fig. 11a, b) suggest that the magma was sourced from an isotope-depleted garnet–lherzolite mantle through a moderate degree of partial melting (10–20%). And during the diagenetic process, the separation crystallization mainly occurs with clinopyroxene (Fig. 12). In primitive-mantle-normalized spider plots (Fig. 8b), all the dykes studied show distinct negative anomalies for Nb and Ta, indicating the involvement of crustal components in the mantle source (Zhang *et al.* 2005). The depleted mantle source can be further supported by the zircons from mafic dykes studied, because zircons are obviously recycled and should come from the fusion of depleted mantle sources.

5.b. Crustal contamination

Crustal pollution can lead to the enrichment of Sr–Nd isotopic composition of the basaltic rocks (Guo *et al.* 2004). The positive K, Pb and Zr, negative Nb, Ta and Ti anomalies, low Nb/Ta ratios (3.36–4.88; average 4.18) and relatively uniform La/Nb and higher Ba/Nb ratios (3.5–6.0, 94–466) (Table 3) suggest the contribution of a mantle source related to or contaminated by subducted material (Fig. 8a, b; Guo *et al.* 2013). Although the dolerites studied had a small Sr isotopic composition (~ 0.6969) and positive $\epsilon_{\text{Nd}}(t)$ and $\epsilon_{\text{Hf}}(t)$ values (0.2–0.8, 0.5–8.6, except for a few samples), the possibility that the genetic process is affected by crustal contamination cannot be ruled out. In the related diagrams of Nb/Ta vs La/Yb, Ce/Nb vs Th/Nb, Th/Nb vs Ta/Yb and La/Nb vs Ce/Pb (not shown), there are obvious projection laws of the mafic dyke swarms studied, further implying that the genetic process was affected by obvious crustal contamination. The low Ce/Pb (1.64–6.22) and Nb/U ratios (4.38–10.2) and higher La/Nb (1.28–1.65), Zr/Nb (9.97–15.9) and Rb/Nb ratios (2.61–12.3) also imply this. Crustal contamination would result in significant variation in Sr and Nd isotope compositions. Although there is no obvious correlation between MgO and $(^{87}\text{Sr}/^{86}\text{Sr})_i$, positive correlations between MgO and $\epsilon_{\text{Nd}}(t)$ values are obvious from the dykes

Fig. 3. (Colour online) Representative CL images of zircon grains from samples from the mafic dykes studied.

studied (Fig. 8b; Taylor & McLennan, 1985). Therefore, there was clearly crustal contamination during the formation of these dykes. The mafic dykes are characterized by depletion in Th relative to La (Fig. 8b), eliminating the possibility of significant upper-middle crustal contamination (Taylor & McLennan, 1985). A likely candidate for the contamination might be lower crust.

5.c. Genetic model and tectonic significance

The mafic dykes studied provide possible evidence for the extension of Neoproterozoic lithosphere and the evolution of the lower mantle beneath the NCC. Herein, we propose a genetic model of the dykes studied and the tectonic significance.

Geochemical characteristics show that the parent magma forming the mafic dykes comes from the melting of an isotope-depleted garnet lherzolite mantle (10–20 %). However, all the dykes have significant negative high-field-strength elements (HFSE; e.g. Nb, Ta, P and Ti) and positive Pb and K anomalies in the normalized multi-element plots compared to the original mantle (Table 3; Fig. 8a, b). In general, HFSE deficiency (i.e. Nb, Ta) is interpreted

as rutile fractionation (Table 3; Fig. 8b; Zhang *et al.* 2005). In addition, the positive anomaly of Pb and K is considered to be the result of mixing and metasomatism of fluids from subducted oceanic plates in the mantle source region (Nelson, 1992; Rogers & Setterfle, 1994; Chung *et al.* 2001; Muller *et al.* 2001).

The high Ba/Nb ratios (51–215; Table 3) of these dykes are different from most intraplate volcanic rocks (i.e. ocean island basalt, alkaline basalt and kimberlite), and their Ba/Nb ratios are very low (from 1.0 to 20; Jahn *et al.* 1999). Therefore, the above data suggest that the mantle-derived magma that generated these has assimilated possible crustal contamination.

Many processes related to plume-related magmatism and mantle chemical heterogeneity (Arndt & Goldstein, 1989; Kay & Kay, 1991; Rudnick & Fountain, 1995; Jull & Kelemen, 2001; Gao *et al.* 2004; Elkins-Tanton, 2005; Lustrino, 2005; Anderson, 2006) are closely related to the subsidence of continental lower crust to convective mantle. As eclogite has higher density than peridotite of lithospheric mantle (Rudnick & Fountain, 1995; Jull & Kelemen, 2001; Anderson, 2006; Levander *et al.* 2006), eclogite material will be easier to recycle into the mantle (Arndt & Goldstein, 1989; Kay

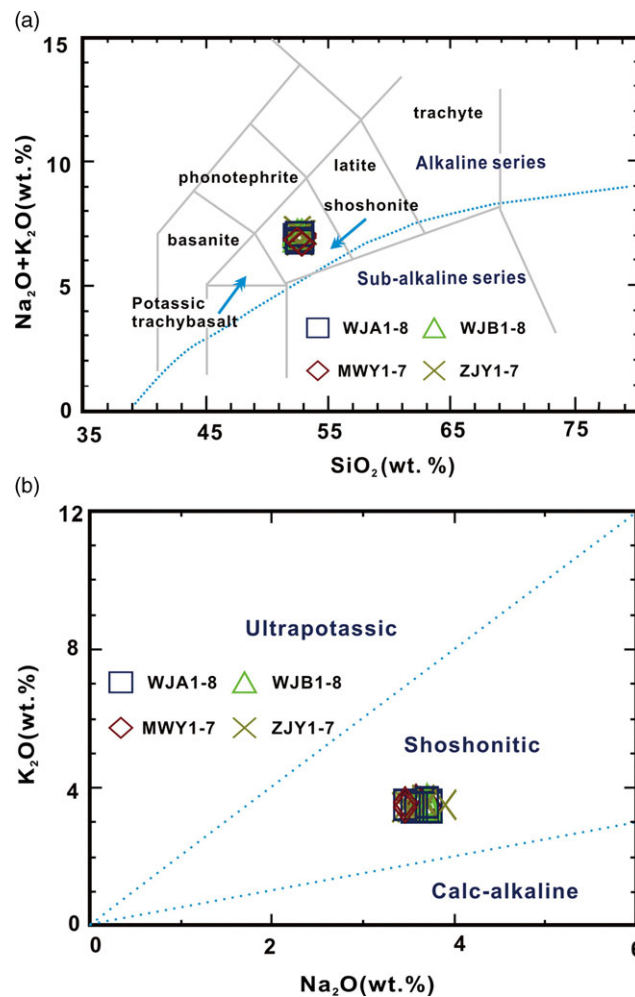

Fig. 5. (Colour online) Classification of the mafic dykes studied. (a) Total-alkali silica (Middlemost, 1994; Le Maitre, 2002) using major element concentrations recalculated to 100% volatile-free compositions. (b) variations in K_2O vs Na_2O concentrations (Menzies & Kyle, 1972).

& Kay, 1991; Jull & Kelemen, 2001; Gao *et al.* 2004, 2008). Moreover, if the eclogite is silicon-saturated, it can hybridize with the overlying mantle peridotite and produce olivine-free pyroxene. The subsequent melting of these pyroxenes in the mantle can produce basaltic magma (Kogiso *et al.* 2003; Sobolev *et al.* 2005, 2007; Herzberg *et al.* 2007; Gao *et al.* 2008). Therefore, this model has been used to explain the origin of the mafic dyke parent magmas in the NCC (Liu *et al.* 2008a, b, 2009, 2013b).

In general, mafic dyke swarms can provide significant scientific information for the time and stage of extensional tectonics, and are ideal objects for studying mantle plume activity and lithospheric extension (Hou, 2012). Previous studies in the NCC focused on Mesozoic, Cenozoic and Proterozoic mafic dykes and documented three episodes of lithospheric extension during the Proterozoic (i.e. from 1.8 to 1.6 Ga, 1.3 to 1.2 Ga, and 0.8 to 0.7 Ga). Nevertheless, study of the extension of NCC Archaean (age > 2.5 Ga) lithosphere is still very weak (Chen & Shi, 1983, 1994; Chen *et al.* 1992; Shao & Zhang, 2002; Zhang & Sun, 2002; Peng *et al.* 2005, 2007, 2008,

2010, 2011a, b; Hou *et al.* 2006; Yang *et al.* 2007; Li *et al.* 2010; Peng, 2010). The age data and genetic model in this paper are of considerable significance for basaltic magma activities in the lower crust related to the extension of the Archaean lithosphere. It has been suggested that the large-scale continental accretion and Archaean cratonization (2.5–2.6 Ga) occurred in the southwest and northeast of present-day Shandong province (Wang *et al.* 1999; Hou *et al.* 2004). Generally, the thickened crust will undergo eclogite, and then sink and recycle back to the underlying mantle (Arndt & Goldstein, 1989; Kay & Kay, 1991; Jull & Kelemen, 2001; Gao *et al.* 2004). The foundered eclogite has a higher density than that of the mantle peridotite (Rudnick & Fountain, 1995; Jull & Kelemen, 2001; Anderson, 2006; Levander *et al.* 2006), but its melting temperature is lower than that of mantle peridotite (Yaxley & Green, 1998; Rapp *et al.* 1999; Yaxley, 2000; Kogiso *et al.* 2003; Sobolev *et al.* 2005, 2007). This means that the heating of silicon-saturated eclogite will produce an intermediate acid solution assemblage (from tonalite to

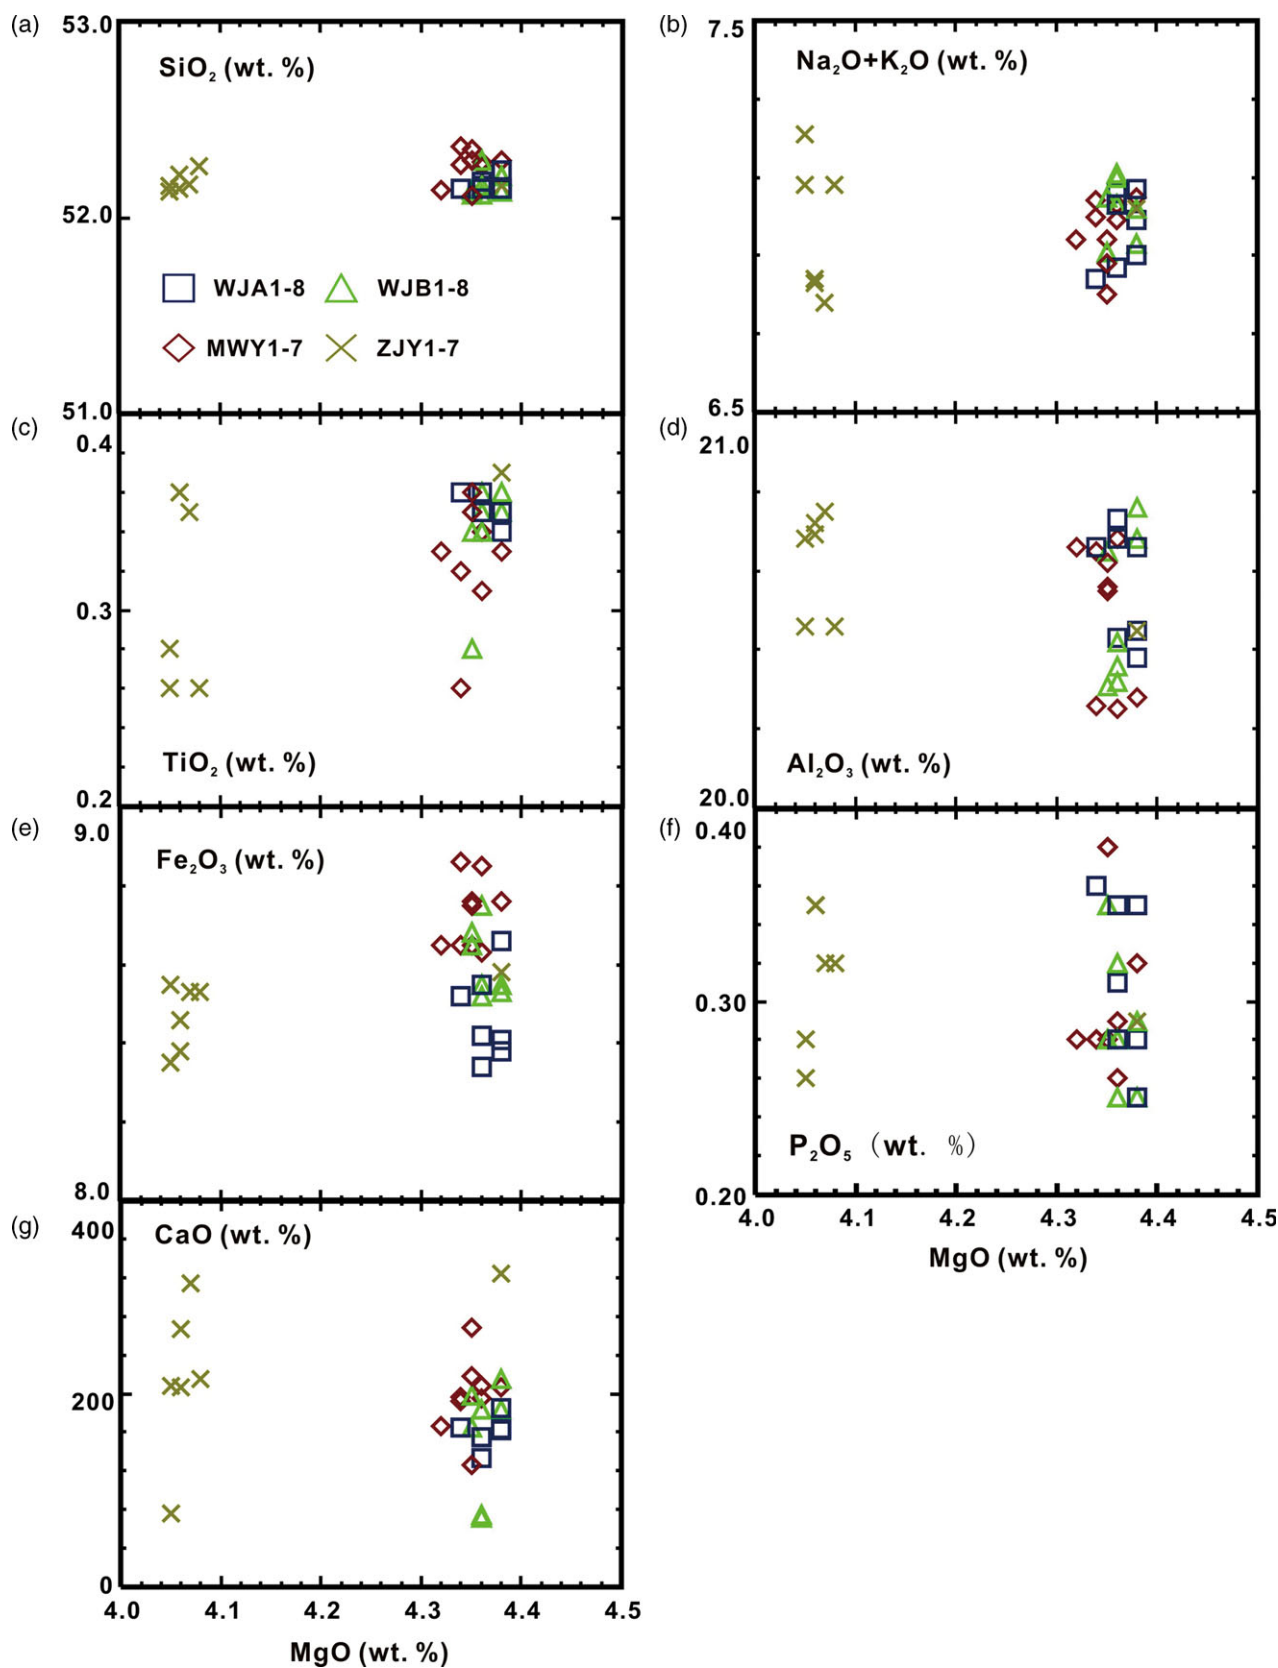

Fig. 6. (Colour online) Variations in major element concentrations vs MgO (wt %) for the mafic dykes studied.

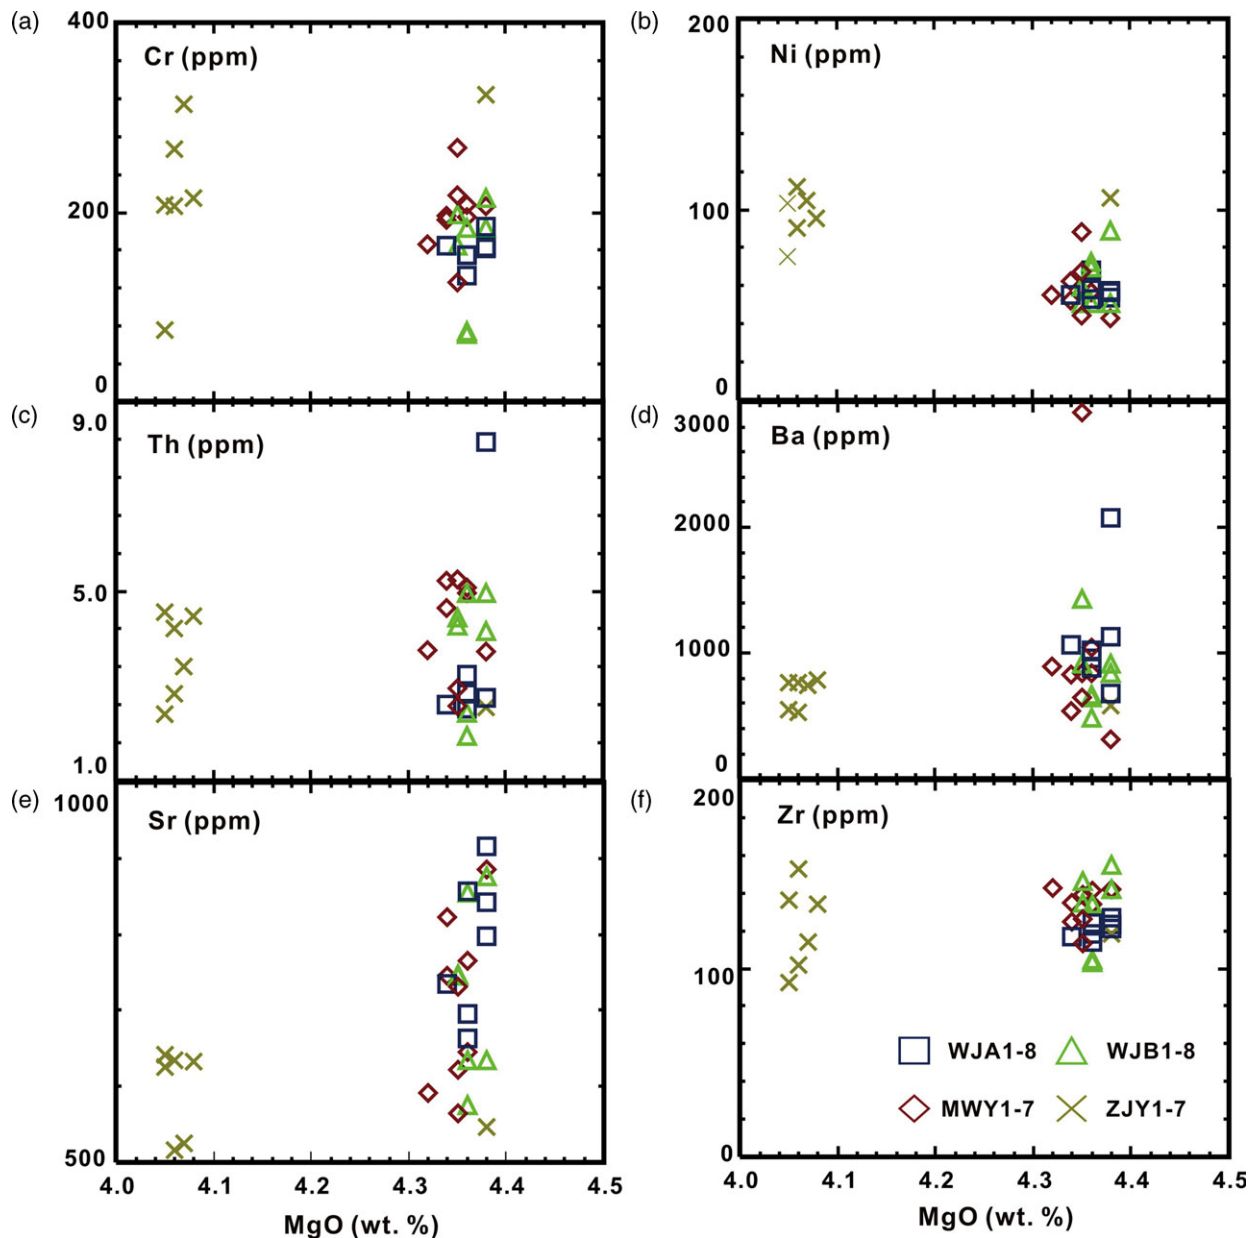

Fig. 7. (Colour online) Variations in trace element concentrations vs MgO (wt %) for the mafic dykes studied.

trondhjemite), rather than basic solution. These melts can be hybridized with mantle peridotite overlying areas to varying degrees. Subsequently, decompression melting of mixed mantle can produce basaltic melt (Kogiso *et al.* 2003; Sobolev *et al.* 2005, 2007; Herzberg *et al.* 2007; Gao *et al.* 2008). Nevertheless, the lithospheric mantle in western Shandong province is not highly enriched, which may be the result of limited hybridization between the mantle and the subsidence lower crust. Subsequently (~2.5 Ga), the partial melting of the slightly mixed mantle will produce the parent magma of the dykes studied. These magmas intruded into the Earth's crust and formed these mafic dykes between ~2.51 Ga and 2.54 Ga. The layered model is further supported by the geochemical composition, which is similar to that of the igneous rocks

derived from the layered dynamic model: enrichment in Ba, K, Pb, Sr and Zr, negative HFSE (Nb, Ta and Ti), $(La/Yb)_N$ (7.17–8.55), relatively low $\epsilon_{Nd}(t)$ (0.2–0.8) and $\epsilon_{Hf}(t)$ ratios (–2.8 to 8.6) (Tables 3–5; Figs 7–9; Wedepohl, 1991; Gao *et al.* 1992; Budnick, 1995; Gao & Jin, 1997; Feng *et al.* 2012; Qi *et al.* 2012; Liu *et al.* 2006, 2008a, b, 2009, 2010b, 2010c, 2011, 2012b, 2013a, 2013c, 2014, 2015, 2016, 2017, 2018; Luo *et al.* 2006), intense lithosphere thinning (Liu *et al.* 2008a, b), massive contemporaneous magmatic activity (Regional Geology of Shandong Province, 1995) and large-scale mineralization appear in the NCC (Regional Geology of Shandong Province, 1995). All of the above phenomena can be explained by the foundering of lithosphere.

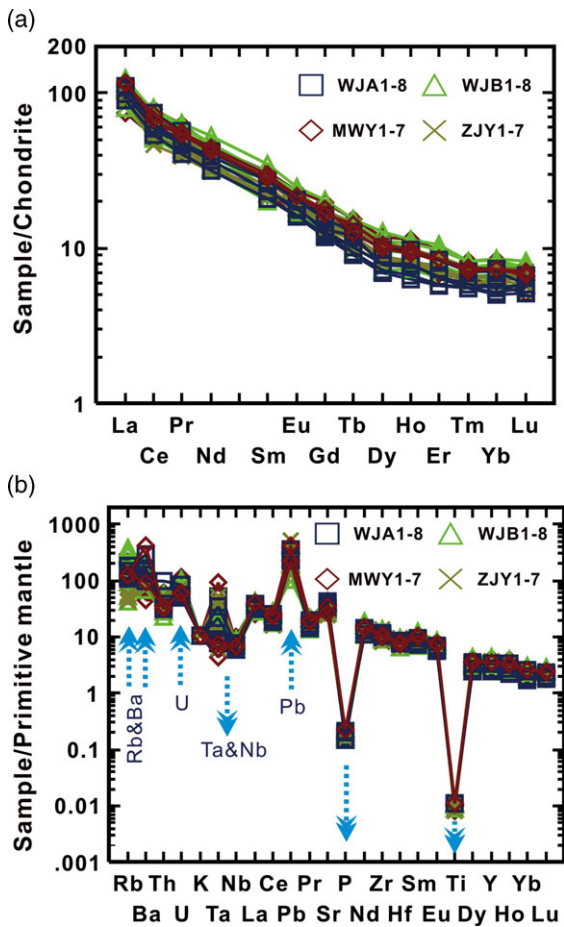

Fig. 8. (Colour online) (a) Chondrite-normalized REE and (b) primitive-mantle-normalized multi-element variation diagrams for the mafic dykes studied. Concentrations are normalized to chondrite composition of Sun and McDonough (1989).

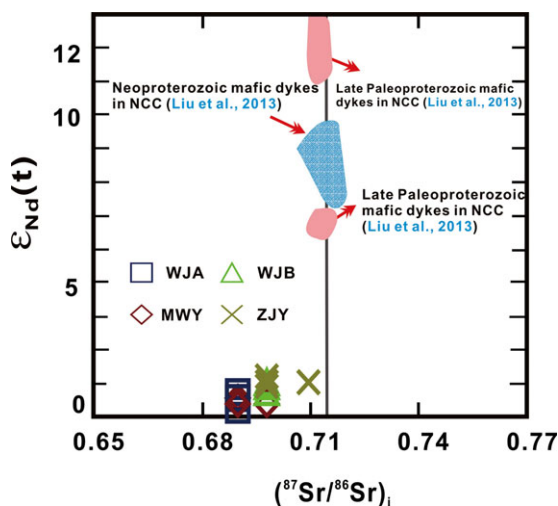

Fig. 9. (Colour online) Variations in initial $^{87}\text{Sr}/^{86}\text{Sr}$ vs $\epsilon_{\text{Nd}}(t)$ values for the mafic dykes studied. The field delineates the composition of Proterozoic mafic dykes within the NCC (Liu *et al.* 2013b). The mafic dykes analysed during this study plot within the isotope-depleted mantle source field.

6. Conclusions

1. Zircon LA-ICP-MS U-Pb dating indicates that the mafic dykes from Shandong province in the northeastern NCC formed between 2509 ± 6.1 and 2537 ± 6.2 Ma, indicative of a Neoproterozoic mafic magmatic event.
2. These mafic dykes are alkaline and shoshonitic. They are characterized by high light rare earth element (LREE) concentrations ($(\text{La}/\text{Yb})_{\text{N}}$ between 7.17 and 8.55), positive Eu (Eu/Eu^* between 1.12 and 1.27), Ba, K, Pb and Sr anomalies,

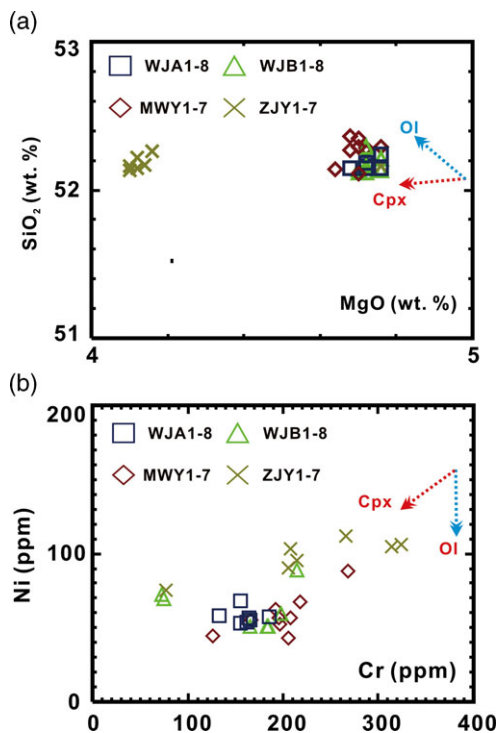

Fig. 12. (Colour online) The correlative plots MgO vs SiO₂ (a) and Cr vs Ni (b) for the mafic dykes studied.

and negative Nb, P, Ta and Ti anomalies. The dykes have low initial ($^{87}\text{Sr}/^{86}\text{Sr}$)_i values of ~0.6969, high $\epsilon_{\text{Nd}}(t)$ (0.2–0.8) and $\epsilon_{\text{Hf}}(t)$ values (0.5–8.6, except for a few samples). They were likely derived from melting (10–20 %) of an isotope-depleted garnet–lherzolite mantle that was hybridized by foundered lower crustal material.

3. The mantle-derived parent magma of the basic vein in the study area was affected by crustal pollution to a certain extent during the magma ascent.

Acknowledgements. This research was supported by the Most Special Fund of the State Key Laboratory of Continental Dynamics, Northwest University, the National Natural Science Foundation of China (41373028, 41573022) and Shaanxi Provincial Natural Science Basic Research Program Project (2023-JC-ZD-16). The authors thank Honglin Yuan and Liang Qi for assistance during zircon Hf isotope, Sr–Nd isotope and trace element analyses, and the zircon U–Pb dating.
