(Received 17 July 2013; revised 2 January 2014; accepted 16 February 2014; first published online 19 March 2014)

This study investigates the collision statistics of inertial particles in inverse-cascading two-dimensional (2D) homogeneous isotropic turbulence by means of a direct numerical simulation (DNS). A collision kernel model for particles with small Stokes number (St) in 2D flows is proposed based on the model of Saffman & Turner (J. Fluid Mech., vol. 1, 1956, pp. 16-30) (ST56 model). The DNS results agree with this 2D version of the ST56 model for $St \leq 0.1$. It is then confirmed that our DNS results satisfy the 2D version of the spherical formulation of the collision kernel. The fact that the flatness factor stays around 3 in our 2D flow confirms that the present 2D turbulent flow is nearly intermittency-free. Collision statistics for St = 0.1, 0.4 and 0.6, i.e. for St < 1, are obtained from the present 2D DNS and compared with those obtained from the three-dimensional (3D) DNS of Onishi et al. (J. Comput. Phys., vol. 242, 2013, pp. 809-827). We have observed that the 3D radial distribution function at contact (g(R)), the so-called clustering effect) decreases for St = 0.4 and 0.6 with increasing Reynolds number, while the 2D g(R) does not show a significant dependence on Reynolds number. This observation supports the view that the Reynolds-number dependence of g(R) observed in three dimensions is due to internal intermittency of the 3D turbulence. We have further investigated the local St, which is a function of the local flow strain rates, and proposed a plausible mechanism that can explain the Reynolds-number dependence of g(R). Meanwhile, 2D stochastic simulations based on the Smoluchowski equations for $St \ll 1$ show that the collision growth can be predicted by the 2D ST56 model and that rare but strong events do not play a significant role in such a small-St particle system. However, the probability density function of local St at the sites of colliding particle pairs supports the view that powerful rare events can be important for particle growth even in the absence of internal intermittency when St is not much smaller than unity.

Key words: multiphase and particle-laden flows, turbulence simulation, turbulent flows

1. Introduction

Several mechanisms have been proposed in the literature to explain what causes the fast size broadening of cloud droplets, which could result in quick rain initiation at the early stage of cloud development. Examples are enhanced collision rates of cloud droplets by turbulence (Falkovich & Pumir 2007; Grabowski & Wang 2009, 2013), turbulent entrainment (Blyth 1993; Krueger, Su & McMurtry 1997), giant cloud condensate nuclei (Yin et al. 2000; Van Den Heever & Cotton 2007) and turbulent dispersions of condensing cloud droplets (Sidin, Ijzermans & Reeks 2009). The most intensely discussed is the first mechanism: enhanced collision rate by turbulence. This has initiated extensive research on particle collisions in turbulence (Sundaram & Collins 1997; Wang, Wexler & Zhou 2000; Saw et al. 2008; Onishi, Takahashi & Komori 2009; Dallas & Vassilicos 2011, and references therein). There are several collision models that predict collision rates of particles in turbulence. Saffman & Turner (1956) analytically derived a collision model for particles with zero or very small Stokes number, St (St = τ_p/τ_η , where τ_p is the particle relaxation time and τ_η is the Kolmogorov time), while Abrahamson (1975) derived a model for particles with much larger τ_p than T_l , the integral time scale of the turbulence. Water droplets typically have $St = O(10^{-2})$ to $O(10^{0})$, and $St = O(10^{0})$ to $O(10^{2})$ when they are rain droplets. One difficulty arises from the preferential motion of inertial particles. Inertial particles preferentially cluster and accumulate in regions of low vorticity and high strain if St < 1 (Maxey 1987; Chun *et al.* 2005), and cluster in such a way as to mimic the clustering of zero-acceleration points by the sweep-stick mechanism if $1 \lesssim St \lesssim \tau_p/T_I$ (Coleman & Vassilicos 2009). This matters because clustering increases the mean collision rate (Sundaram & Collins 1997). The clustering effect makes the construction of a fully analytical model for finite-inertia particles very difficult, and requires several empirical parameters in collision models (Wang et al. 2000; Zhou, Wexler & Wang 2001; Zaichik, Simonin & Alipchenkov 2003; Onishi 2005; Franklin, Vaillancourt & Yau 2007). Those parameters are usually determined by direct numerical simulation (DNS) data. Data from laboratory experiments (Saw et al. 2008; Lu et al. 2010; Bordas et al. 2011) would, of course, help, but available data are very limited.

One serious problem is that the Reynolds-number dependence of turbulent collisions has not yet been clarified. The Taylor-microscale-based Reynolds number R_{λ} ($R_{\lambda} = u'l_{\lambda}/v$, where u' is the root mean square of the velocity fluctuations, l_{λ} is the Taylor microscale and v is the kinematic viscosity) for collision statistics attained by DNS is $R_{\lambda} = O(10^2)$. This value is much smaller than those in cloud turbulence, where R_{λ} ranges from 10³ up to nearly 10⁵. (It is often estimated as R_{λ} of 10³ to 10⁴ in the literature. However, R_{λ} is estimated to be up to $(5-8) \times 10^4$ in MacPherson & Isaac (1977), and Siebert, Lehmann & Wendisch (2006) observed R_{λ} of $(3-4) \times 10^4$.) Nevertheless, there are several studies where collision models are used in cloud simulations to investigate the impact of enhanced collisions of cloud droplets (Onishi *et al.* 2006; Xue, Wang & Grabowski 2008; Wang *et al.* 2009; Onishi, Takahashi & Komori 2011). These studies simply extrapolate their collision statistics for high- R_{λ} flows, which requires high-performance computing.

Onishi, Takahashi & Vassilicos (2013) recently extended the upper limit in R_{λ} by DNS. They attained $R_{\lambda} = 530$ and reported a dependence of collision statistics on Reynolds number for $R_{\lambda} > 100$. They observed that the clustering effect, and consequently the collision kernel, decreases as R_{λ} increases for $R_{\lambda} > 100$ and St = 0.4, while no significant Reynolds-number dependence was observed for St = 0.1. This is a

relevant and significant observation, since many authors ignore this Reynolds-number dependence and assume a constant collision kernel irrespective of R_{λ} (Saffman & Turner 1956; Derevyanko, Falkovich & Turitsyn 2008; Zaichik & Alipchenkov 2009) or assume a convergence to a constant collision kernel with increasing R_{λ} (Ayala, Rosa & Wang 2008). A similar Reynolds-number dependence for St < 1 has now been confirmed by Rosa *et al.* (2013). Onishi *et al.* (2013) anticipated that this Reynolds-number dependence might be due to the intermittent nature of high-Reynolds-number turbulence. However, no evidence for this has been obtained so far.

The present study, therefore, aims to obtain evidence that the intermittent nature of small-scale turbulence influences the collision statistics, leading to this Reynoldsnumber dependence. To achieve this goal, the present study utilizes two-dimensional (2D) isotropic turbulence with inverse cascade because such turbulent flows have little internal intermittency (Tabeling 2002), thus allowing an assessment of the significance of intermittency by comparing 2D and three-dimensional (3D) DNS turbulence results. We therefore develop a DNS for colliding inertial droplets in 2D isotropic turbulence with inverse cascade; the code is composed of the flow code by Goto & Vassilicos (2004), the particle code by Dallas & Vassilicos (2011) and the collision statistics code by Onishi *et al.* (2009). Then we compare the present results with the 3D results of Onishi *et al.* (2013).

In order to investigate the role of intermittency, the present study employs intermittency-free inverse-cascading 2D turbulence as a counterpart for comparisons with 3D turbulence, where intermittency is strong. Another option would have been to employ a synthetic flow simulation, such as a phase-shuffled simulation (Yoshimatsu et al. 2009) or a kinematic simulation (Chen, Goto & Vassilicos 2006; Goto et al. 2005, and references therein). The phase-shuffled flow can be obtained by decomposing the DNS velocity field into Fourier modes and randomizing the phases of the coefficients. This method preserves energy, but breaks the flow structure and makes the flow intermittency-free. The phase-shuffled flow has a full set of flow modes, while the kinematic flow has only a fraction of modes. Both flows can mimic the -5/3 power-law energy spectrum and both have intermittency-free, i.e. Gaussian, statistics of fluctuating velocity difference. Yoshimatsu et al. (2009) reported that phase-shuffled turbulence does not preserve the acceleration's scaling behaviour, which implies that the acceleration physics, which are of central importance in particle clustering and collisions, are different from Navier-Stokes turbulence. Chen et al. (2006) reported that, in kinematic simulations of turbulence, particle clustering results from the repelling action of velocity stagnation-point clusters, a clustering mechanism that is very different from those in Navier-Stokes turbulence. These facts suggest that synthetic simulations of turbulence are not the best option for a comparative discussion of the effect of intermittency on particle clustering and resulting Reynolds number dependences. This is why we chose DNS of inverse-cascading 2D turbulence for this purpose.

In the following section, we briefly introduce theoretical results for turbulent collision statistics including the presently derived 2D theoretical results. Our 2D DNS code is presented in § 3. Numerical results and discussion are presented in § 4, which consists of flow statistics in § 4.1 and mostly particle statistics in § 4.2. We conclude in § 5.

2. Collision statistics theories

2.1. Collision kernel for small-Stokes-number particles

The Stokes number is defined as

$$St = \frac{\tau_p}{\tau_\eta},\tag{2.1}$$

where $\tau_p \ (\tau_p = 2\rho_p r^2/(9\rho_a v))$ is the particle relaxation time, with *r* the droplet radius and ρ_p/ρ_a the ratio of the density of liquid water to that of air, and $\tau_\eta \ (\tau_\eta = \sqrt{v/\epsilon})$ is the Kolmogorov time, with *v* the kinematic viscosity and ϵ the energy dissipation rate. The Stokes number *St* is a non-dimensional parameter of particle inertia, and St = 0corresponds to a tracer particle that follows the carrier flow perfectly.

The collision rate per unit area and unit time between a particle of radius r_1 and a particle of radius r_2 is given by

$$N_c(r_1, r_2) = K_c(r_1, r_2) n_{p1} n_{p2}, \qquad (2.2)$$

where K_c is the collision kernel, and n_{p1} and n_{p2} are droplet number concentrations. Saffman & Turner (1956) derived the collision kernel for $St \ll 1$ in 3D isotropic turbulence as

$$\langle K_c(r_1, r_2) \rangle_{\text{ST,3D}} = \sqrt{2\pi} R^2 \left[\left(1 - \frac{\rho_a}{\rho_p} \right)^2 (\tau_{p1} - \tau_{p2})^2 \overline{\left(\frac{\text{D}u}{\text{D}t} \right)^2} + \frac{1}{3} \left(1 - \frac{\rho_a}{\rho_p} \right)^2 (\tau_{p1} - \tau_{p2})^2 g^2 + \frac{1}{15} \lambda^2 R^2 \right]^{1/2},$$
 (2.3)

where $\langle \cdots \rangle$ denotes an ensemble average, r_1 and r_2 are the radii of each particle, $\lambda = 1/\tau_{\eta}$, g is the gravitational acceleration and $R = r_1 + r_2$ is the collision radius. Neglecting gravity and using $\rho_a/\rho_p \ll 1$, the above equation becomes

$$\langle K_c(r_1, r_2) \rangle_{\text{ST,3D}} = \sqrt{2\pi} R^2 \left[(\tau_{p1} - \tau_{p2})^2 \overline{\left(\frac{\mathrm{D}u}{\mathrm{D}t}\right)^2} + \frac{1}{15} \lambda^2 R^2 \right]^{1/2}.$$
 (2.4)

The first term in the square brackets is the acceleration contribution, and the second is the shear contribution. When $r_1 = r_2$, i.e. for the monodisperse case, the acceleration contribution disappears because $\tau_{p1} = \tau_{p2}$ and we obtain

$$\langle K_c(r_1, r_1) \rangle_{\text{ST,3D}} = \sqrt{\frac{2\pi}{15}} \lambda R^3.$$
(2.5)

The 15 in the square root originates from the relation $\epsilon/\nu = 15\langle (\partial u/\partial x)^2 \rangle$ for 3D isotropic turbulence (Taylor 1935). Two-dimensionality reduces the freedom in dimension, leading to $\epsilon/\nu = 8\langle (\partial u/\partial x)^2 \rangle$. This leads to collision kernels for bidisperse droplets and monodisperse droplets with $St \ll 1$ in 2D isotropic turbulence as

$$\langle K_c(r_1, r_2) \rangle_{\text{ST,2D}} = \sqrt{2\pi} R \left[(\tau_{p1} - \tau_{p2})^2 \overline{\left(\frac{\mathrm{D}u}{\mathrm{D}t}\right)^2} + \frac{1}{8} \lambda^2 R^2 \right]^{1/2}$$
 (2.6)

and

$$\langle K_c(r_1, r_1) \rangle_{\text{ST,2D}} = \frac{\sqrt{\pi}}{2} \lambda R^2,$$
 (2.7)

respectively.

2.2. The spherical formulation

Wang, Wexler & Zhou (1998b) formulated the collision kernel in 3D flows based on the spherical formulation as

$$\langle K_c(r_1, r_2) \rangle_{3\mathrm{D}} = 2\pi R^2 \langle |w_r(x=R)| \rangle g(x=R), \qquad (2.8)$$

where $w_r(x = R)$ (w_r hereafter) is the radial relative velocity at contact, and g(x = R) (g(R) hereafter) is the radial distribution function (RDF) at contact. The RDF g(R) represents the clustering effect and is equal to unity when particles are uniformly distributed. One important assumption behind (2.8) is that the relative velocity is incompressible, thus influx and outflux across the sphere surface are equal. The collision kernel is then half the surface area multiplied by the average magnitude of the radial relative velocity and by g(R).

Based on the same assumption, the 2D version of the spherical formulation can be derived as

$$\langle K_c(r_1, r_2) \rangle_{2\mathrm{D}} = \pi R \langle |w_r| \rangle g(R).$$
(2.9)

3. Two-dimensional direct numerical simulation

3.1. Flow simulation

The code developed by Goto & Vassilicos (2004) was used to generate a 2D statistically stationary homogeneous isotropic turbulent flow in a periodic box of length 2π with an inverse energy cascade giving rise to an energy spectrum $\propto k^{-5/3}$. The DNS scheme integrates in time the modified vorticity ($\boldsymbol{\omega}$) equation,

$$\frac{\partial \boldsymbol{\omega}}{\partial t} = \nabla \times (\boldsymbol{u} \times \boldsymbol{\omega}) + \hat{D} \boldsymbol{\omega} + \boldsymbol{f}, \qquad (3.1)$$

in wavenumber space using a fourth-order Runge–Kutta scheme, with the nonlinear term calculated in real space, i.e. a pseudo-spectral method is adopted. Here u is the fluid velocity and f is the external forcing to maintain a statistically stationary state. The forcing acts only on the Fourier components in the wavenumber range between k_f and βk_f (β is a constant, slightly larger than 1). The dissipation operator \hat{D} is defined as

$$\hat{D} = [-\nu\Delta^8 + \alpha\Delta^{-1}], \qquad (3.2)$$

and allows for large-scale dissipation in 2D flows through hyper-drag (α term). The high-order (specifically eighth-order) hyper-viscosity ensures that the small-scale enstrophy dissipation does not contaminate inertial-range statistics. This choice (3.2) of dissipation operator produces a well-defined $k^{-5/3}$ energy spectrum. More details on this 2D turbulence simulation can be found in Goto & Vassilicos (2004) and Faber & Vassilicos (2010).

The numerical choices for the 2D flows are summarized in table 1. In order to prevent the forcing from directly affecting particle motions, wave motions with $k > k_c$, where $k_c = k_f/1.2$ (Dallas & Vassilicos 2011), were filtered out from the fluid velocity field used to calculate particle trajectories and statistics as well as related flow statistics. In order to compare the present 2D results with the 3D results of Onishi *et al.* (2013), we introduce the following Reynolds number:

$$Re_T = \frac{T_I}{\tau_n}.$$
(3.3)

Rur	1	N^2	k_f	β	ν	L_I	u'	Re_T
N64	4 (64 ²	13	1.08	$9.0 imes 10^{-19}$	0.696	6.12	6.12
N12	28 1	28 ²	26	1.04	2.5×10^{-23}	0.606	5.20	8.32
N25	56 2	256^2	51	1.02	8.0×10^{-28}	0.536	4.35	11.3
N5	12 5	512^{2}	102	1.01	2.5×10^{-32}	0.467	3.38	16.4

N20	048 20	048^{2}	410	1.0025	2.0×10^{-41}	0.355	2.13	30.5
N40	096 40	096 ²	819	1.00125	$6.0 imes 10^{-46}$	0.281	1.35	41.1
TABLE	1. Para	meters	for the	e 2D isotr	opic turbulen	ce with	inverse	cascade.

Here T_I is the integral time $(T_I = L_I/u')$, with u' the root mean square of the fluctuating velocity and L_I the integral length $(L_I = \pi/2u'^2 \int_0^\infty E(k)k^{-1}dk)$, with E(k) the energy spectrum), and τ_η is calculated as $\tau_\eta = 1/\sqrt{2\langle \operatorname{tr}(s^2) \rangle}$, with *s* the strain-rate tensor, whose components $s_{ij} = (\partial_i u_j + \partial_j u_i)/2$ are obtained after low-pass filtering at $k = k_c$. This Re_T is proportional to $(L_I/\eta)^{2/3}$, where $\eta = (\nu^3/\epsilon)^{1/4}$ is the Kolmogorov scale, for the 3D homogeneous isotropic turbulence, and to $(L_I/l_c)^{2/3}$, where $l_c = 2\pi/k_c$, for the 2D one.

3.2. Particle simulation

Water droplets are considered as Stokes particles with inertia governed by the equation

$$\frac{\mathrm{d}\boldsymbol{v}(\boldsymbol{x}_p)}{\mathrm{d}t} = -\frac{1}{\tau_p}(\boldsymbol{v}(\boldsymbol{x}_p) - \boldsymbol{u}(\boldsymbol{x}_p)), \qquad (3.4)$$

where v is the particle velocity and x_p is the particle position. Onishi *et al.* (2009) showed that gravity is not a relevant factor for collisions of monodisperse small water droplets in a 3D homogeneous isotropic turbulence, and Onishi *et al.* (2013) simply neglected gravity. For the sake of comparisons with Onishi *et al.* (2013), this study also neglects gravity. The fourth-order Runge–Kutta method was used for time integration of particle positions and velocities. The flow velocity at a particle position was interpolated using fifth-order Lagrangian interpolation. Turbulence modulation by droplets was assumed negligible because of high particle dilution.

There are several ways to deal with collision events. One of the colliding droplets may be removed immediately after collision (scheme 1), or droplets may be allowed to overlap (ghost-particle condition) (scheme 2). Scheme 1 is more realistic because the collision-coalesced droplet will form a particle of larger size and will disappear from the original size group. Scheme 2 is suitable for discussing the so-called spherical form (refer to (2.8) and (2.9)), where the effect of clustering is clear. In order to include a discussion of the clustering effect, this study employs scheme 2.

After the 2D background airflow reached a statistically stationary state, water droplets were introduced into the flow. Collision detection was then started after a period exceeding 30 times the integral time T_I . The collision rate between particles r_1 and r_2 at the *n*th time step $N_c^n(r_1, r_2)$ is calculated from the number of collision pairs $N_{col,pair}^n(r_1, r_2)$ detected in the domain for a time interval Δt as $N_c^n = N_{col,pair}^n/(S_d \Delta t)$, where S_d is the area of the computational domain. Thus, the collision kernel at the

FIGURE 1. Energy spectra of the present 2D flow.

*n*th time step, K_c^n , is obtained as

$$K_c^n(r_1, r_2) = \frac{N_{col, pair}^n(r_1, r_2)}{n_{p1} n_{p2} S_d \Delta t},$$
(3.5)

where $n_{pi} = N_{pi}/S_d$, where N_{pi} (i = 1, 2) is the total number of particles with radius r_i and $S_d = (2\pi)^2$. The mean collision kernel, $\langle K_c \rangle$, is calculated by time averaging the collision kernels over the duration of the collision simulation. The radial relative velocity at contact $\langle |w_r| \rangle$, and the RDF at contact g(R) are calculated based on the algorithm of Wang *et al.* (2000). A method based on molecular-dynamic-simulation strategies was employed for detecting neighbouring pairs (Allen & Tildesley 1987; Sundaram & Collins 1996).

4. Results and discussion

4.1. Flow statistics

Figure 1 shows energy spectra for all the runs listed in table 1. As Goto & Vassilicos (2004) reported, the constancy of the energy flux is achieved in the inertial range, leading to a -5/3 power law. A vertical needle shape is observed at the forcing scale, i.e. at $kl_c = 1.2$; it is filtered out by the low-pass filter at $k = k_c$.

Figure 2 shows the flatness factor defined as

$$F = \frac{\langle (\partial u_1 / \partial x_1)^4 \rangle}{\langle (\partial u_1 / \partial x_1)^2 \rangle^2}.$$
(4.1)

The flatness factor for the 3D flow increases as Re_T increases, while that for the present 2D flow stays around 3 and is at most 4, which suggests a near-Gaussian distribution for $\partial u_1/\partial x_1$. This confirms that the 3D turbulence becomes more intermittent with increasing Reynolds number, while the 2D turbulence does not (to be fully accurate, its flatness factor systematically increases but the rate is

FIGURE 2. Flatness factor against Re_T .

much less than that of 3D turbulence) (Tabeling 2002). The skewness *S*, defined as $S = \langle (\partial u_1/\partial x_1)^3 \rangle / \langle (\partial u_1/\partial x_1)^2 \rangle^{3/2}$, was also investigated and confirmed to be $O(10^{-2})$ for all the runs in the present 2D flow (not shown).

4.2. Collision statistics

4.2.1. Spherical formulation

The radial relative velocity at contact, $\langle |w_r| \rangle$, and the RDF at contact, g(R), are calculated following the algorithm by Wang *et al.* (2000), where pairs with interparticle distance *d* such that $R - \delta/2 < d \leq R + \delta/2$ are considered as contacting pairs. Wang *et al.* (2000) investigated the δ dependence of $\langle |w_r| \rangle$ and g(R), and observed that the two statistics are insensitive to δ if $\delta/R < 0.2$. They investigated this dependence for 3D homogeneous isotropic turbulence, but no study has yet investigated it for a 2D flow.

Figure 3 shows the dependence of $\langle |w_r| \rangle$ and g(R) on δ for the N256 run. The error bars were obtained from more than five runs, each run lasting for a time $33T_I$. It can be seen that $\langle |w_r| \rangle$ increases with increasing δ because slightly larger sizes of eddies of larger velocity fluctuations will contribute to the relative velocity. On the other hand, g(R) decreases with increasing δ because the level of preferential concentration is reduced by a larger shell volume. It is also observed that $\langle |w_r| \rangle$ and g(R) are insensitive to δ for $\delta/R < 0.2$. These observations agree well with those of Wang *et al.* (2000). Following Wang *et al.* (2000), this study adopts $\delta = 0.02R$ from here onwards.

The collision kernels directly obtained from (3.5) using our DNS were compared with the collision kernels obtained from (2.9) and found to deviate by 0.8% for St = 0.4, consistent with the errors of nearly 1% previously reported in 3D DNS of homogeneous isotropic turbulence (Wang, Wexler & Zhou 1998*a*; Onishi *et al.* 2013).

4.2.2. Stokes-number dependence of collision statistics

Figures 4 and 5 show the Stokes-number dependence of collision statistics for the N2048 run, where the flow contained $1\,024\,000$ particles in total. Figure 4(a)

FIGURE 3. Dependence of (a) the radial relative velocity at contact, $\langle |w_r| \rangle$, and (b) the radial distribution function at contact, g(R), on the thickness of the spherical shell, δ .

shows the collision kernel normalized by λR^2 . The collision kernels for small inertial particles where $St \leq 0.04$ are in good agreement with (2.7), while those for larger inertial particles are significantly larger than (2.7) due to their inertia. This tendency is very similar to that observed in 3D flows (e.g. Wang *et al.* (2000)). Figure 4(*b*) shows the residual RDF defined as g(R) - 1. For $St \ll 1$, an analytical solution predicts that $g(R) - 1 \propto St^2$ (Wang *et al.* 2000). This holds for $St \leq 0.04$ in the figure. Figure 4(*c*) shows the radial relative velocity at contact normalized by λR . From (2.7) and (2.9), and assuming $g(R) \sim 1$, we obtain $\langle |w_r| \rangle / \lambda R = 1/2\sqrt{\pi} = 0.282$. The 2D DNS results agree with the line of 0.282 for $St \leq 0.1$.

Figure 5 shows the Stokes-number dependence of calculated collision kernels for bidisperse droplets. The same number of different-size droplets were introduced into the fully developed 2D isotropic turbulence for calculating the collision kernel. The Stokes number of one group of droplets was fixed at $St_1 = 0.04$, whereas that of the other group was varied between $St_2 = 0.04$ and $St_2 = 1$. The vertical axis in figure 5 is the collision kernel $K_c(St_1 = 0.04, St_2)$ normalized by λR^2 . The present 2D DNS results agree with (2.6) for $St_2 \leq 0.2$ but not with (2.7) except for the case where $St_1 = St_2$. This confirms that the acceleration contribution is important if not dominant when collisions are between different-size droplets.

FIGURE 4. Stokes-number dependence of collision statistics of monodisperse droplets in the 2D isotropic turbulence.

FIGURE 5. Stokes-number dependence of collision statistics of bidisperse droplets in the 2D isotropic turbulence. The horizontal axis shows St_2 , while St_1 was fixed at 0.04.

All the figures in this subsection have shown that the present 2D DNS results agree with theoretical predictions for $St \ll 1$, in fact, roughly speaking, for St < 0.1. This confirms the reliability of the present code and statistical procedures used in this study.

4.2.3. Collision growth of small inertial particles

Dallas & Vassilicos (2011) showed a rapid growth of particles with initially very small inertia, specifically St = 0.04, in DNS of 2D homogeneous isotropic turbulence with -5/3 energy spectrum. They concluded that powerful rare events had led to the rapid growth in their system. However, what we have observed so far in this study is that collision frequencies for such small inertial particles in such flows follow the Saffman & Turner (1956) theory. This subsection aims to clarify whether such powerful rare events do indeed violate the stochastic framework (consistent with the Saffman & Turner theory) at very small Stokes numbers. We perform two kinds of collision growth simulations: one is based on a stochastic (kinematic) framework, which requires collision kernels as inputs, and the other on Lagrangian integration obtained from our DNS framework. We then compare results to check whether the collision growth in the Lagrangian framework can be predicted by the stochastic framework.

Let us suppose that initially we have monodisperse droplets of type 1. Larger droplets will form by multiple collisions, and we denote by n_s the number concentration of droplets with *s* times the mass of a type 1 droplet. The radius of type *i* droplets is $r_i = i^{1/3}r_1$, and consequently their Stokes number is $St_i = i^{2/3}St_1$. We also assume that when two droplets collide they coalesce without bouncing nor breaking up. Then the following equation holds (called the Smoluchowski equation or stochastic collision equation):

$$\frac{\mathrm{d}n_i}{\mathrm{d}t} = \sum_{l+m=i} K^{\#}_{lm} n_l n_m - \sum_{j=1}^{\infty} K_{ij} n_i n_j.$$
(4.2)

Here $K_{lm} = K_c(r_l, r_m)$ and $K_{lm}^{\#}$ is $\frac{1}{2}K_{lm}$ for l = m and K_{lm} otherwise. Table 2 shows the collision kernels $K_{lm}^{\#}$ for bidisperse systems obtained from our 2D DNS as described in § 3.2. Two more ways of calculating $K_{lm}^{\#}$ are considered in this study: equations (2.6) (i.e. shear plus acceleration terms) and (2.7) (i.e. shear term only).

Following Dallas & Vassilicos (2011), we calculated the collision growth of droplets from a Lagrangian procedure applied to our DNS of 2D turbulence. The computational settings were basically the same as those of Dallas & Vassilicos (2011), with 2048² grid points and 1.5×10^6 droplets. The one single difference was that the initial droplet size distribution was purely monodisperse in this study while it had small deviations in Dallas & Vassilicos (2011). We checked that the small deviations have little influence. Figure 6 shows the distributions of droplet sizes at $t/T_I = 9.5$. There were initially only s = 1 particles, and, as the collision growth proceeds, larger *s* particles were created. As the initial number of droplets was $1.5 \times 10^6 \sim O(10^6)$ for

FIGURE 6. Distribution of droplet sizes produced from an initially uniform population at $t/\tau_L = 9.5$. LAG(2D DNS) refers to the result obtained from a Lagrangian procedure applied to our 2D DNS, STO($K_c =$ Eq. (2.7), i.e., shear only), STO($K_c =$ Eq. (2.6), i.e., shear + accel.) and STO($K_c =$ 2D DNS) refer to results obtained by solving the stochastic equation (4.2) with three different ways of obtaining collision kernels.

the Lagrangian DNS, there is no possibility for n_s/n_{ini} (where n_{ini} is the initial number concentration) to drop below 10^{-6} in the present Lagrangian DNS result. However, the calculations based on the stochastic equation (4.2) give values of n_s/n_{ini} smaller than 10^{-6} , as indeed seen in the figure. It is clear from figure 6 that the stochastic result with the collision kernel of (2.7) underestimates the growth speed, while the result with the collision kernel of (2.6) slightly overestimates it. This observation corresponds to what we observed in figure 5 (which showed an underestimate by (2.7) in the collision kernels and an overestimate by (2.6) and also confirms the relevance of the acceleration term in (2.6). The stochastic result with the collision kernels pre-calculated from DNS (see table 2) agrees with the Lagrangian DNS result. This indicates two relevant points: One is that the Lagrangian DNS and the stochastic simulations are both reliable. The other is that the stochastic approach, without considering a special treatment for powerful rare events, can predict the collision growth in this turbulence. This shows that the rapid collision growth observed in Dallas & Vassilicos (2011) can be explained by the classical stochastic framework. It should be noted, however, that Dallas & Vassilicos (2011) focused on the droplets in atmospheric clouds and adopted a system of small inertial particles with a dilute volume fraction. The mechanism they proposed may nevertheless be valid for larger St particles and/or with more dense volume fractions. This will be partly discussed in §4.2.6.

4.2.4. Reynolds-number dependence of collision statistics

Figure 7(*a*) shows the mean collision kernel obtained for St = 0.4 from the present 2D DNS together with that from the 3D DNS of Onishi *et al.* (2013). The 3D DNS was performed for the flow with R_{λ} ranging from 49 to 527. The largest simulation,

FIGURE 7. (a) Collision kernel, (b) radial distribution function and (c) radial relative velocity at contact for St = 0.4 plotted against Re_T .

i.e. $R_{\lambda} = 527$ simulation, was performed using 2000³ grid points and one billion particles. Please refer to Onishi *et al.* (2013) for more details on the numerical schemes and procedures of the 3D DNS. The collision kernels are normalized by λR^2 and λR^3 for the 2D and 3D results, respectively. The error bars show ±1 standard deviation. The standard deviation for two dimensions was obtained from more than three runs, with each run lasting for a time ranging from $5T_I$ to $8T_I$, except for the N64 runs ($Re_T = 6.1$) where the time duration was $44T_I$. The particle size, *r*, was $0.00525l_c$, meaning that *r* was much smaller than the cut-off filter scale. The total number of particles, N_p , was larger for larger grid number simulations so as to maintain the area fraction ϕ_A ($\phi_A = \pi r^2 N_p/(2\pi)^2$) constant. Particle number N_p was 1000 for N64 and up to 4096 000 for N4096. The area fraction ϕ_A was 3.78×10^{-3} , which corresponds to a high dilution, thereby suggesting only binary collisions. The normalized collision kernel from the 3D DNS decreases for $Re_T > 7$ (corresponding to $R_{\lambda} > 100$) as noted by Onishi *et al.* (2013). In contrast, that from the present 2D DNS does not decrease in the Reynolds-number range $10 < Re_T < 40$.

Figure 7(*b*,*c*) shows the RDF and radial relative velocity at contact, i.e. g(R) and $\langle |w_r| \rangle$, respectively. In the present 2D DNS, g(R) decreases with increasing Reynolds number at low values of Re_T but then becomes constant for $Re_T > 16$. By contrast, the 3D g(R) increases at low values of Re_T but then decreases for $Re_T > 7$. Furthermore, the 3D data of Onishi *et al.* (2013) in figure 7 show, as indeed concluded by Onishi *et al.* (2013), that the Reynolds-number dependence of the collision kernel reflects,

in three dimensions, the Reynolds-number dependence of g(R). Indeed, as seen in figure 7, the 3D g(R) shows a similar Reynolds-number dependence to the 3D collision kernel, whereas the 3D $\langle |w_r| \rangle$ does not. (Note, however, that the 3D $\langle |w_r| \rangle$ slowly increases towards what appears to be a constant value, and this weak trend cancels some of the decreasing trend of the 3D g(R), causing the collision kernel to decrease with increasing Re_T at a slightly slower rate than g(R).) In two dimensions, the radial relative velocity at contact $\langle |w_r| \rangle$, the RDF g(R) and the collision kernel all remain approximately constant or very slowly varying with Re_T . This observed difference between two and three dimensions is consistent with the anticipation by Onishi *et al.* (2013) that the intermittency may be the cause of the Reynolds-number dependence of the collision statistics in 3D turbulence.

4.2.5. Local flow statistics

With the aim to gain some insight into the effect of internal intermittency on the collision kernel, we investigate in this subsection the probability density functions (PDFs) of $s^* = \sqrt{2 \operatorname{tr}(s^2)}$ (for both three and two dimensions) and $\epsilon^* = \nu s^{*2}$ (for three dimensions). Note that *St* (the characteristic global Stokes number) can be written as $St = \tau_p / \tau_\eta = \tau_p \sqrt{2 \langle \operatorname{tr}(s^2) \rangle}$.

The non-dimensional local flow strain rate, σ^* , is defined as

$$\sigma^* = \begin{cases} s^* \tau_\eta & \text{for two dimensions,} \\ \sqrt{\epsilon^*/\epsilon} & \text{for three dimensions,} \end{cases}$$
(4.3)

where $\epsilon = \nu \langle s^{*2} \rangle$. This definition leads to $\int \sigma^{*2} \text{PDF}(\sigma^*) d\sigma^* = 1$ as $\langle s^{*2} \rangle \tau_{\eta}^2 = 1$. Figure 8 shows the PDFs of the local flow strain rate, σ^* , and the mean values of σ^* , i.e. $\langle \sigma^* \rangle$, against Re_T . Figure 8(*a*) shows that the most likely σ^* , i.e. σ_{likely}^* (where the PDF reaches its maximum), is smaller than unity and the probability of $\sigma^* > 3$ is negligibly small. It also shows that σ_{likely}^* decreases with increasing Re_T and that the decrease rate is larger in three than in two dimensions. This trend is quantitatively mirrored in figure 8(*b*), which shows that the 3D $\langle \sigma^* \rangle$ decreases with increasing Re_T and that the 2D $\langle \sigma^* \rangle$ also decreases but at a smaller rate. This difference in the Reynolds-number dependence is in line with the fact that the 3D flows have a stronger Reynolds-number dependence of the flatness factor (see figure 2).

The decrease of σ_{likely}^* indicates that, as Re_T increases, an increasing part of space is dominated by low local strain rates. Here, let us define the local Stokes number, St^* , as $St^* = \sigma^* St$. Then the decreasing σ^*_{likely} with increasing Re_T is interpreted as a decreasing St^*_{likely} (where the PDF reaches its maximum), as illustrated in figure 9, where St_{likely}^* is always smaller than unity, since we limit the discussion for St < 1in this study. The schematic illustration can explain, under the assumption that the clustering is strong for $St^* \sim 1$, the decreasing dependence of g(R) on Re_T . As Re_T increases, an increasing part of space is dominated by low local strain rates, i.e. small $St^*(<1)$, which would imply lower values of g(R), while the extreme strain rates increase in an increasingly small area of space. As the area of $St^* > 1$ cannot efficiently increase g(R), the extreme strain rates cannot tip the balance and overcome the reduction in g(R) caused by the reduced values of local strain rates in most of the space. This mechanism for decreasing g(R) could work as far as the extreme strain rates of $St^* > 1$, i.e. $\sigma^* > 1/St$, hold some influence on the statistics. According to the PDFs in figure 8(a), the probability of $\sigma^* > 3$ is negligibly small. Therefore, the mechanism would not work when $St \ll 1/3$, in which case the extreme

FIGURE 8. (a) Probability density functions and (b) mean values of the local strain rate, σ^* .

strain rates may tip the balance and compensate the reduction in g(R) caused by the reduced values of local strain rates in most of the space, making the g(R) insensitive to the Reynolds number.

In order to support our argument on the Reynolds-number dependence of g(R), we extend our discussion to two more Stokes numbers. Figure 10 shows g(R) against Re_T for three different Stokes numbers: St = 0.1, 0.4 and 0.6. The data for St = 0.4 are the same as in figure 7(*b*), but the vertical axis is differently arranged. In figure 10(*b*,*c*), the right axes are for 3D data and the left axes for 2D data. The ranges of the right and left axes are in the same ratio, i.e. 9–21 for the right, and 6–14 for the left in figure 10(*b*) in order to focus on the trend. The 3D DNS data for St = 0.1 and 0.6 have been obtained for the present study with almost the same numerical schemes and data processing for St = 0.4 in Onishi *et al.* (2013). The sole difference from Onishi *et al.* (2013) is in the run duration for the smallest Re_T (corresponds to the 3D simulation for $R_A = 49$ with 64³ grids and 32³ particles): each run duration for the smallest Re_T for St = 0.1 and 0.6 was four times larger than the other 3D DNS data in order to decrease the standard deviation.

FIGURE 9. Schematic illustration of the mechanism of the decreasing clustering effect with higher Reynolds number with stronger intermittency.

FIGURE 10. Radial distribution function at contact, g(R), plotted against Re_T for (a) St = 0.1, (b) St = 0.4 and (c) St = 0.6.

Data for St = 0.1 (i.e. $\ll 1/3$) are almost constant, or at least do not show any clear Reynolds-number dependence, as predicted by our argument based on figure 9. By contrast, for St = 0.4 and 0.6, 2D and 3D data show variations against Re_T . The Reynolds-number dependences for small Reynolds numbers are affected by the limited

FIGURE 11. Probability density function of the non-dimensional local Stokes number of colliding pairs of particles, σ_c^* .

computational domain sizes. Here we focus on the Reynolds-number dependence in the range of larger Reynolds numbers where Re_T is bigger than $Re_{T,crit}$ ($Re_{T,crit}$ differs in different data sets). For St = 0.6, as in the case of St = 0.4, the 3D g(R)decreases with Reynolds number in the range of $Re_T > Re_{T,crit}$, while the 2D g(R)almost converges towards an approximately constant value. This further supports our argument illustrated in figure 9. Note that $Re_{T,crit}$ has a dependence on St. For St = 0.4it is 7 and 16 for three and two dimensions, respectively, and for St = 0.6 it is 10 and 23 for three and two dimensions, respectively. That is, $Re_{T,crit}$ becomes larger for larger St. This may be caused by larger-St particles being influenced by larger flow motions with larger time scales, which would require larger domain sizes (i.e. larger Re_T) for this artificial effect to be eliminated. The present study limits the discussion to St < 1, thus targeting the cloud droplets. A discussion of the Reynolds dependence of larger-St particles would require larger Re_T data sets.

4.2.6. Local particle statistics

The non-dimensional local Stokes number of colliding pairs of particles can be defined as

$$\sigma_c^* = St_{col}^*/St, \tag{4.4}$$

where St_{col}^* is the local Stokes number at the location where the two particles collide. (Since all the particles have the same size in the system and the separation between the two colliding particles (i.e. *R*) is negligibly small compared to the grid size Δ , we can safely assume that St_{col}^* is the same for both particles. Therefore, only one of the two possible St_{col}^* is processed.) Figure 11 shows the PDFs of σ_c^* . For both three and two dimensions, the right tails of the PDFs become thicker, i.e. the relative frequencies of strong events become larger with increasing Re_T . Interestingly, the Re_T dependence of the tail thickness in two dimensions looks comparable with its counterpart in three dimensions. In order to quantify the Re_T dependence of the relative frequency of strong events, we define the probability of strong events as

$$P(\sigma_c^* \ge 2) = \int_2^\infty \text{PDF}(\sigma_c^*) \, \mathrm{d}\sigma_c^*. \tag{4.5}$$

FIGURE 12. Probability for the case that $\sigma_c^* (= St_{col}^*/St)$ exceeds 2.

Figure 12 shows $P(\sigma_c^* \ge 2)$ against Re_T . In two dimensions $P(\sigma_c^* \ge 2)$ depends on Re_T and increases with increasing Re_T . This suggests that, even with little intermittency as is the case in two dimensions, the impact of rare but strong events increases with increasing Re_T . The argument by Dallas & Vassilicos (2011) that strong rare collision events enhance collision growth in high-Reynolds-number turbulence irrespective of internal intermittency (even if not supported for extremely small inertial particles in § 4.2.3) may nevertheless be valid for non-negligibly small inertial particles. This mechanism, which distinguishes between powerful rare collision events and internal intermittency, requires a future study of its own based on new simulations run for larger values of *St* and Re_T .

5. Conclusions

In this study, we have developed a direct numerical simulation (DNS) of colliding inertial particles in two-dimensional (2D) isotropic turbulence. The 2D DNS code is composed of the flow code by Goto & Vassilicos (2004), the particle code by Dallas & Vassilicos (2011) and the collision statistics code by Onishi et al. (2009). Using this combined code, we have investigated, for the first time, the detailed collision statistics in 2D isotropic turbulence. Firstly, the 2D version of the collision kernel model by Saffman & Turner (1956) for small-Stokes-number particles, $St \ll 1$, has been formulated. It has then been confirmed that the DNS results agree with the present 2D formulation. In turn, this confirmed the reliability of both the present 2D DNS code and the present formulation. Secondly, we have modified the spherical formulation for three-dimensional (3D) flows (Wang et al. 1998b) in order for it to be applicable in two dimensions. The Lagrangian pair radial relative velocity, $\langle |w_r| \rangle$, and the radial distribution function at contact, g(R), depend on the thickness of the contact shell, δ . We have observed a very similar dependence of $\langle |w_r| \rangle$ and g(R) on δ in two dimensions as previously observed in three dimensions by Wang et al. (2000). As a result, the value of δ was fixed at $\delta = 0.02R$, as in Wang *et al.* (2000), in this study. It has been confirmed that $g(R) - 1 \propto St^2$ and $\langle |w_r| \rangle / \lambda R = 1/2\sqrt{\pi}$ (=0.282) for $St \ll 1$ in the present 2D flow.

The 2D DNS results have been compared with the 3D DNS data of Onishi *et al.* (2013) for St = 0.4 and with newly obtained 3D DNS data for St = 0.1 and 0.6. Onishi *et al.* (2013) reported that, for St = 0.4, the collision kernel decreases with increasing

Reynolds number, reflecting the decreasing trend of the clustering effect. This study has investigated the role of turbulence intermittency in the Reynolds-number dependence. The 3D turbulence has internal intermittency, while the 2D turbulence has virtually none (Tabeling 2002). This has been confirmed in terms of the flatness factor $F = \langle (\partial u_1 / \partial x_1)^4 \rangle / \langle (\partial u_1 / \partial x_1)^2 \rangle^2$. We have observed that the clustering effect for the 3D flow decreases for St = 0.6 as well as for St = 0.4 in large-Reynolds-number ranges with increasing Reynolds number, while that for the 2D flow does not show a clear Reynolds-number dependence in the corresponding large-Reynolds-number range. This observation supports the view that the Reynolds-number dependence of the clustering effect observed in three dimensions is due to internal intermittency of the 3D turbulence. We have further investigated the local flow strain rates (σ^*) and confirmed that an increasing part of space is dominated by low σ^* as the Reynolds number increases, i.e. as the flow intermittency grows. This means that, as the Reynolds number increases, an increasing part of space is dominated by small St*, where St^* is the local Stokes number defined as $St^* = \sigma^* St$, which would decrease g(R) when the most likely σ^* is smaller than unity. As the area of $St^* > 1$ cannot efficiently increase g(R), the extreme strain rates cannot overcome the reduction in g(R) caused by the reduced values of local strain rates in most of the space. This mechanism for decreasing g(R) could work as far as the extreme strain rates of $St^* > 1$, i.e. $\sigma^* > 1/St$, hold some influence on the statistics. The probability of $\sigma^* > 3$ is negligibly small. Therefore, the mechanism would not work when $St \ll 1/3$, in which case the extreme strain rates may compensate the reduction in g(R) caused by the reduced values of local strain rates in most of the space, making the g(R)insensitive to the Reynolds number.

A comparison between the 2D Lagrangian DNS and a stochastic simulation has revealed that the collision growth observed in Dallas & Vassilicos (2011) for initially St = 0.04 particles can be predicted by the conventional stochastic approach. However, for Stokes numbers not much smaller than unity (e.g. St = 0.4), the PDF of local Stokes numbers sampled at the collision sites of particle pairs indicates that local strong collision events become increasingly frequent with increasing Reynolds number even in 2D inverse-cascading turbulence, i.e. irrespective of the internal intermittency of the turbulence.

Acknowledgements

This research was conducted while Ryo Onishi was receiving a JSPS postdoctoral fellowship for research abroad. The large-size three-dimensional numerical simulations presented were carried out on the Earth Simulator 2 supercomputer in the Japan Agency for Marine–Earth Science and Technology (JAMSTEC), and the two-dimensional simulations on the JAMSTEC supercomputer system. The 2D code developed in this study is based on the flow code provided by Dr Susumu Goto and the particle code provided by Dr Vassilios Dallas. The authors sincerely appreciate their kindness.
